those which are not in contact, via neighboring soft particles.² The effect of the magnetic field treatment on the magnetic properties of the $Nd_8Fe_{77}Co_5B_6CuNb_3$ ribbons at different temperatures of annealing is illustrated in Fig. 2. Ribbons subjected to the magnetic field and heat treated at 700 °C for different duration present different behavior of the magnetic characteristics. One can note that the magnetic

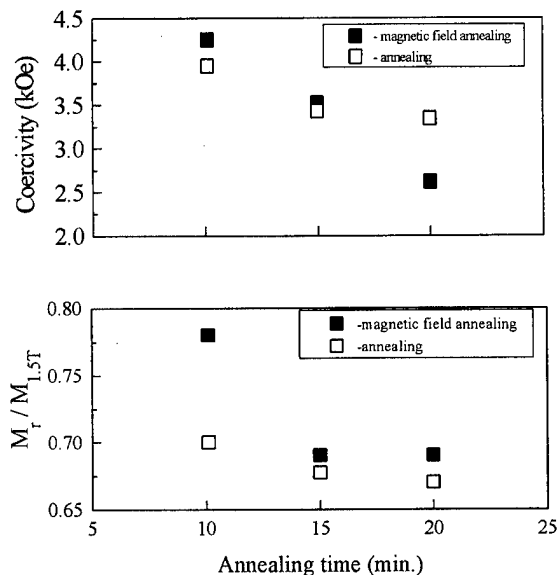

FIG. 2. Coercivity and remanent ratio $M_r/M_{1.5T}$ of the melt-spun $Nd_8Fe_{77}Co_5B_6CuNb_3$ ribbons as a function of annealing time with and without applied magnetic field.

FIG. 3. Hysteresis loops of the melt-spun $Nd_8Fe_{77}Co_5B_6CuNb_3$ ribbons annealed at 700 °C for 10 min with and without applied magnetic field.

properties obtained by performing heat treatments are improved by applying simultaneously a magnetic field.

The remanence ratio is enhanced by applying a magnetic field. This result supports the assumption that the exchange coupling between magnetic phases is increased. The biggest enhancement in the $M_r/M_{1.5T}$ values is of 13% and corresponds to the treatment for which the maximum in coercivity is reached meaning that the grains behave as single-domain particles (see Fig. 1).

Figure 3 illustrates the effect of the magnetic field applied during the heat treatment at 700 °C for 10 min on a hysteresis loop. The enhancement of the $M_r/M_{1.5T}$ ratio by the applied magnetic field supports the assumption that the exchange coupling between magnetic phases is increasing. Figure 4 presents the thermomagnetic curve for the $Nd_8Fe_{77}Co_5B_6CuNb_3$ ribbons. It follows that Co atoms are simultaneously diffused in $Nd_2Fe_{14}B$ as well as in α -Fe and increase the corresponding Curie temperatures from the characteristic values of the above mentioned phases (316 °C and 770 °C) up to about 360 °C and 820 °C, respectively. This increase is due only to the Co content.

FIG. 4. Thermomagnetic curve of $Nd_8Fe_{77}Co_5B_6CuNb_3$ ribbons magnetic field annealed at 700 °C for 10 min.

IV. CONCLUSION

Summarizing, the addition of Cu and Nb leads to the improvement of the magnetic properties as a result of the nanocrystalline structure. The addition of Co results in an $\sim 50^\circ\text{C}$ increase in the Curie temperature of both hard and soft magnetic phases. The magnetic field annealing of the melt-spun $\text{Nd}_8\text{Fe}_{77}\text{Co}_5\text{B}_6\text{CuNb}_3$ amorphous ribbons leads to improvement of the hard magnetic properties. The obtained

results suggest that the magnetic field applied during annealing determines a uniform mixture of the soft and hard component magnetic phases.

Rapidly solidified samples of $\text{Nd}_{9.5}\text{Fe}_{84.5}\text{B}_6$ with and without 3 at. % TiC were prepared by melt spinning and melt extraction and then annealed in vacuum (3×10^{-6} Torr) at temperatures from 600 to 750 °C. For alloys melt spun under similar conditions, the overquenched state was achieved at wheel speeds >10 m/s for the TiC added alloy while >20 m/s was necessary without TiC. The overquenched samples contained a smaller fraction of α -Fe in smaller grains than the undercooled samples where Fe dendrites formed near the free surface during solidification. These Fe dendrites were not removed by annealing. In addition, large orientated 2-14-1 grains nucleated on the Fe dendrites. This combination is detrimental to the magnetic properties. The addition of TiC results in improved control of the microstructure over a larger fraction of the ribbon volume enhancing the magnetic properties. © 1998 American Institute of Physics. [S0021-8979(98)31511-X]

I. INTRODUCTION

To achieve enhanced remanence in Nd-Fe-B alloys, numerous groups have shown that adding excess Fe and B improves the exchange coupling effect.¹⁻⁴ The formation of secondary phases is dependent on the initial composition, melt-spinning parameters, and subsequent heat treatment. Additions of TiC have been shown to improve the quenchability and inhibit grain growth during subsequent annealing for stoichiometric 2-14-1.⁵ A study of the effect of TiC addition on a high remanence alloy was undertaken to see if TiC addition provides better quenchability and microstructural control during subsequent annealing. The effect of processing and composition on microstructure will be discussed in light of a new model for rapid solidification in peritectic systems.^{6,7}

II. EXPERIMENTAL TECHNIQUES

$\text{Nd}_{9.5}\text{Fe}_{84.5}\text{B}_6$ with and without 3 at. % TiC was melt spun from 5 to 25 m/s in Ar then annealed in vacuum (3×10^{-6} Torr) at temperatures from 600 to 750 °C. The TiC added alloy is designated HRT, the alloy without TiC, HR1. The microstructure of these samples was compared to samples of $\text{Nd}_{9.5}\text{Fe}_{84.5}\text{B}_6$ melt-extracted at 45 m/s and annealed in a similar manner. The samples were analyzed using differential thermal analysis (DTA) to determine glass fraction, dc superconducting quantum interference device (SQUID) magnetometry to determine energy product, and vibrating sample magnetometry (VSM) to characterize Fe content. Microstructure and phase composition were studied

by transmission electron microscopy (TEM) and x-ray diffraction (XRD). TEM samples were prepared by mounting the ribbons onto Cu ovals and Ar ion milling at 5 keV using a liquid nitrogen cooled stage. XRD was performed on ground and sieved ($<38 \mu\text{m}$) powder and on ribbon surfaces. XRD on the wheel and free surfaces was previously shown to indicate variations in phase compositions and the presence of texturing in underquenched ribbons of stoichiometric 2-14-1 composition.⁷ The optimally quenched state as a function of wheel speed was determined by the maximum in the energy products before heat treatment while the overquenched state was achieved when the energy product was effectively zero (i.e., primarily glass).

III. BACKGROUND

To explain the evolution in microstructures in melt-spun Nd-Fe-B, the following model, based upon previous work on eutectic alloys, was developed.⁸ The microstructure predicted by this model depends on the degree of undercooling achieved before nucleation occurs on the wheel surface. For the slightly undercooled condition, γ -Fe dendrites solidify under a relatively low driving force which results in thick dendrites with numerous side-arms. When the material cools below the peritectic temperature, 2-14-1 nucleates epitaxially on the Fe with $(111)_{\gamma\text{-Fe}} \parallel (330)_{2-14-1}$ and $[1-10]_{\gamma\text{-Fe}} \parallel [001]_{2-14-1}$. Due to nucleation on the side-arms as well as the dendrite trunks, no significant texture of the 2-14-1 is observed. Under moderate undercooling conditions, 2-14-1 nucleates and grows rapidly. But before the growth front reaches the free side of the ribbon, growth front temperature recedes to the peritectic temperature. Since $T_{\text{peritectic}}$ is significantly below T_{liquid} , Fe dendrites then grow

^{a)}Electronic mail: mjkrmer@ameslab.gov

FIG. 1. TEM bright field image of melt-extracted alloy annealed for 10 min at 600 °C. Note the large Fe dendrites with secondary branches.

rapidly into the remaining liquid in the direction of the temperature gradient without side-arm formation. At the same time the initial 2-14-1 dendrites break up forming a layer seeded with 2-14-1 nuclei. The solidified ribbon consists of two layers, an equiaxed fine-grained 2-14-1 layer and an oriented coarse-grained 2-14-1 structure which nucleated from the Fe dendrites. At optimum undercooling, the 2-14-1 dendrites grow through enough of the ribbon to seed the entire ribbon so that when the dendrite breakup occurs following recalescence, a fine-grained equiaxed microstructure is formed. If the undercooling is sufficiently high, the critical undercooling rate for glass formation is reached in the layer of the ribbon on the wheel surface. The undercooling rate in the interior of the ribbon is lower and hence nucleation may occur after a finite thickness of glass is formed. On the other hand, at sufficiently high rates, the entire ribbon is glassy.

IV. RESULTS

Based on TEM and XRD results, the melt-extracted alloy obviously formed in the slightly undercooled state. The XRD and VSM data show a large fraction of free Fe phase as expected from the stoichiometry (~ 17 vol % as determined by VSM). Large Fe dendrites were also observed in the TEM (Fig. 1). This is also supported by the low energy product which was not substantially changed with annealing. Higher undercooling was achieved with melt-spinning wheel speeds >10 m/s. Based on magnetization data and XRD, HR1 was near its optimal quench at 15 m/s while it took only 10 m/s for HRT (Table I). Previous work showed that optimal as-spun magnetic properties are achieved with moderate undercooling.⁹ After annealing, the magnetic properties of both samples showed a slight decrease, most likely due to grain growth of the grains near optimal size. The XRD shows a substantial Fe peak for both samples. This is predicted in the model since a small fraction of the ribbon will recalescence to the $T_{\text{peritectic}}$, where primary Fe will form.

The overquenched state was achieved at wheel speeds >10 m/s for HRT while >20 m/s was necessary for HR1. The largest energy product for a given wheel speed was obtained using a 700 °C anneal for 10 min for both alloys. For the various wheel speeds, the highest energy product was obtained for those alloys melt-spun in the over quenched state, 15 m/s for TiC added (14.1 MGOe) and 20 m/s without TiC (12.4 MGOe), regardless of the annealing temperature. For the TiC added alloy, there is a drop in energy product with increasing wheel speed much beyond the optimal

TABLE I. Maximum energy product (BH_{max}) measured on B rich, high remanence alloys in the as-spun state and after 700 °C anneal for 10 min.

Wheel speed (m/s)	HR1 (without TiC)		HRT (with TiC)	
	As-spun (MGOe)	700 °C (MGOe)	As-spun (MGOe)	700 °C (MGOe)
5	0.36	0.18	0.5	0.6
10	3.04	1.85	2.5	4.6
15	10.1	6.26	0	14.13
20	3.29	12.43	0	12
25	0	11	0	12.3

quench rate. The largest difference in magnetic properties between HRT and HR1 alloys after annealing was at 15 m/s while at 20 and 25 m/s the alloys showed similar properties. Here the improved energy product of the HRT alloy is primarily due to an increase in its coercivity compared to HR1. In fact, the remanence for HR1 at 20 and 25 m/s is better than HRT (Table II).

While 700 °C is high enough to crystallize the amorphous fraction, it is not high enough to cause substantial diffusion over a short time period. This is brought out in the XRD of the free surface of the ribbons (Fig. 2). Note that the HRT alloy shows a typical random pattern for 2-14-1 for both optimal (15 m/s) and overquenched (20 m/s) conditions, while the moderately undercooled HR1 alloy shows distinct texturing of the 2-14-1. As discussed above, the texturing of the 2-14-1 comes about from the growth of Fe during solidification in underquenched ribbons when recalescence raises the temperature of the growth front above the peritectic temperature.

TEM was performed to determine if there are any distinct microstructural differences between the optimally to overquenched and annealed alloys. Dark field images showed little differences in either grain size or percentages of grain boundary (GB) phases except for HRT at 20 m/s which had slightly larger grains and increased GB phases (Fig. 3). The TiC particles were only observed in the GB region. As we expect a microstructural variation through the ribbon thickness, the regions observed may not be representative of the entire ribbon due to the selective nature of TEM. Thus we cannot rule out the existence of significant differences near the ribbon surfaces as demonstrated in the XRD of the free surfaces.

From the solidification model, the formation of γ -Fe occurs after the temperature of the solidification front reaches

FIG. 2. XRD patterns on free sides of (a) HRT alloy and (b) HR1 alloy melt-spun at 15 and 20 m/s then annealed at 700 °C. Note the strong enhancement of the (001) lines for the 2-14-1 phase in the underquenched HR1 alloy which is absent in HRT.

the peritectic temperature but before the liquid composition reaches the composition of the peritectic liquid. If the Fe forms primarily under conditions of high undercooling, fine dendrites form. These dendrites may easily be partially dissolved into the liquid during the solidification of 2-14-1 from the pseudo-equilibrium liquid. This will result in a fine dispersion of small Fe particles which will result in remanence enhancement. If the Fe dendrites form under low undercooling conditions, the dendrites are coarser. As a result the Fe which remains after solidification is larger than the optimum size and possibly large enough to promote reverse domain formation. It appears that for Fe rich compositions, the undercooling required to ensure rapid dendritic growth is such that a limited amount of glass is formed during initial solidification. A short term anneal is sufficient to crystallize this glass without promoting significant grain growth. As in the stoichiometric material, the addition of TiC alters the growth kinetics so that more uniform microstructure may be obtained throughout the ribbon.

Selection of elemental additions and processing conditions to modify the microstructure can be guided by the model presented here. Additions must show considerable solubility in the melt, yet limited solubility in the primary solidification phase, 2-14-1. Appropriate additions can provide solute drag on the primary solidification features, providing more time for the growth front to reach the free boundary. Solidification conditions must provide sufficient undercooling below the peritectic temperature so the dendrites of the primary solidification phase will reach the free boundary before recalescence raises the temperature above peritectic temperature.

FIG. 3. TEM dark field images of samples melt-spun at 20 m/s and then annealed for 10 min: (a) HRT, (b) HR1. The 2-14-1 grain size is approximately 80 nm. The smaller bright grains at the grain boundaries are mostly T/C [as determined by electron energy-loss spectra (EELS)] while the grain boundary phases were predominately Fe and Nd.

A shock compaction technique has been successfully applied for the consolidation of hard magnetic powders without appreciable changes in the phase structure and grain size. Pr-Fe-B and Sm-Fe-N materials, prepared with the application of melt spinning and mechanical alloying, respectively, were shock compacted with a shock wave speed of 1200 m/s and a pressure of 4.4 GPa. We found that the coercivity of high RE containing material, for which the magnetic hardness is controlled by good magnetic separation of magnetic grains by a RE-rich paramagnetic phase, decreases slightly, by $\sim 5\%$, due to the closer proximity of the crystallites in a dense material. For low RE, exchange coupled materials, the densification does not change the coercivity. © 1998 American Institute of Physics. [S0021-8979(98)21611-2]

I. INTRODUCTION

Fully dense, RE-based, permanent magnets are usually made either by liquid phase sintering¹ or by hot working of melt-spun ribbon or mechanically alloyed powder^{2,3}. Recently, a new type of nanocomposite material containing hard and soft magnetic phases (RE-Fe-B- α Fe, Sm-Fe-N- α Fe) with nanoscale grain size have been developed⁴⁻⁶. The improved magnetic properties of these materials are derived from ferromagnetic exchange coupling between the highly refined hard magnetic grains and from the presence of the α Fe, which in both alloys has a higher saturation magnetization than the respective phase. Hard magnetic phases for these materials are Nd₂Fe₁₄B and Sm₂Fe₁₇N₃, respectively. Their crystal structures are tetragonal for the former and rhombohedral for the latter with the easy magnetization directions parallel to the crystallographic *c* axes. The nanocrystalline materials are isotropic. However, hot working at high temperatures, which is usually used for consolidation and texture formation for microcrystalline materials, deteriorates the nanocrystalline microstructure and leads to decomposition of low temperature stability phases such as Sm₂Fe₁₇N₃. Thus, the commonly used method of consolidation of nanophase materials is currently based on resin or metal bonding which substantially reduces the remanence due to the presence of, typically, ~ 20 vol. of nonferromagnetic binder.

Shock compaction of powders is one of the alternative consolidation techniques which enables production of bulk solids while avoiding prolonged heating⁷. This relatively new method involves a variety of processes which utilize rapid deposition of energy in the powder by shock waves.

The application of shock compaction was already reported for the processing of bulk Sm-Fe-N magnets^{8,9}. Promising results were achieved by Mashimo *et al.*¹⁰ who produced shock compressed Sm-Fe-N anisotropic specimens having the magnetic properties: coercivity, $J_H = 450$ kA/m and remanence, $J_r = 1.14$ T.

In this study shock compaction was applied to the consolidation of both crushed melt-spun ribbon and mechanically alloyed powders. The magnetic properties and microstructures of the resulting consolidated magnets are presented and discussed.

II. EXPERIMENTAL PROCEDURE

Rapidly quenched Pr-Fe-B alloys were prepared as ribbon by melt spinning (MS) of molten alloy on a rotating copper roll at speeds of 18–20 m/s in an argon atmosphere. The meltspun ribbon was pulverized to a fine powder. (Sm_{16.5}Fe_{83.5})_{1-x}N_x and (Sm_{13.5}Fe_{86.5})_{1-x}N_x dense compacts were processed by mechanical alloying (MA) in a ball mill, in an argon atmosphere for 50 h. The mechanically alloyed powder was annealed at 700 °C for 1 h and subsequently nitrided at 460 °C for 3 h. The powders were initially cold pressed up to 80% density (specimens - 8 mm diameter by 6 mm height) and subsequently shock compacted using explosives at a pressure of 4.4 GPa within a time of 0.1–1 μ s. The shock wave speed was 1200 m/s¹¹.

The magnetic properties were measured using a vibrating sample magnetometer (VSM) and a pulsed field hysteresisgraph in magnetic fields up to 5 T. Microstructural investigations were carried out using a Jeol 3010 transmission electron micrograph (TEM) equipped with an energy dispersive spectrometer.

(Sm _{16.5} Fe _{83.5}) _{1-x} N _x	1900	0.42	1860	0.51	40	0.53

III. RESULTS AND DISCUSSION

The major shock compaction parameter, wave speed, was 1200 m/s in this study and was selected on the basis of published data¹⁰. Thus, the difference in a final density observed can be explained by the lack of the wave speed optimisation for particular powder precursor. The mechanically alloyed powder had a mean particle size of $\sim 10 \mu\text{m}$ and a mean crystallite size of $\sim 50 \text{ nm}$. For crushed melt-spun ribbon the mean particle and grain sizes were $\sim 100 \mu\text{m}$ and $\sim 50 \text{ nm}$, respectively. Generally, better densification, $\sim 97\%$ of full density, was achieved for mechanically alloyed Sm–Fe–N powder. A lower value of $\sim 89\%$ of full density was obtained for the Pr–Fe–B crushed melt-spun alloy ribbon. This difference we attribute to the smaller mean particle size for the former. Higher densities were also achieved for alloys having higher RE contents.

The magnetic properties of materials before and after shock compaction are shown in Table I and Fig. 1. Hysteresis loops for low and high Pr containing magnets are shown in Fig. 2. The coercivity (J_H) of shock compressed specimens did not differ significantly from their powder precursors. The remanence (J_r), normalized to a fully dense material, does not change for specimens before and after compressing which indicates that the processing does not significantly affect the phase constitution of the material. This suggestion was further confirmed by x-ray analysis which showed the same phase structures before and after

FIG. 1. Magnetic properties of green compacts (g.c.) and shock compressed (s.c.) Pr_xFe_{94-x}B₆ specimens.

FIG. 2. Hysteresis loops for low and high Pr containing magnets.

compressing (Fig. 3). This is especially important for Sm–Fe–N alloys because the Sm₂Fe₁₇N₃ phase decomposes at $\sim 600^\circ\text{C}$ and the material thus cannot be processed at elevated temperatures. However, the actual remanence depends on the density; it is low for green compacts (about 80% of full density) and increases for shock compressed specimens. This increase was greater for the MA than for the MS specimens, which in the present study showed insufficient density. This was reflected in rather low values of remanence and energy product for the melt-spun specimens.

The effect of shock compaction on the microstructure was studied in detail for (Sm_{13.5}Fe_{86.5})_{1-x}N_x mechanically alloyed powder using TEM (Fig. 4). Following annealing and nitriding the powder had a mean particle size of $\sim 50 \mu\text{m}$ consisting of mainly crystallites of diameter 30–60 nm; however, some isolated large grains of diameter 300–500 nm were also visible. After shock compaction the grains had a greater size distribution with diameters 10–100 nm and a mean diameter of 60 nm. However, the very large grains had disappeared so that the microstructure appeared more homogeneous, evidently due to the fragmentation of the large grains during the rapid compaction. Dark field images showed for larger crystallites, $>50 \text{ nm}$ diameter, the existence of 5 nm sized substructure arising either from local misorientation (microtwins) or chemical inhomogeneities. The major phase was Sm₂Fe₁₇N₃; however, small propor-

FIG. 3. X-ray patterns for MA (Sm_{13.5}Fe_{86.5})_{1-x}N_x material before (a) and after (b) shock compressing.

FIG. 4. TEM micrographs of $(\text{Sm}_{13.5}\text{Fe}_{86.5})_{1-x}\text{N}_x$ shock compressed magnet: (a) and (b) bright and dark field images, respectively, (c) electron diffraction.

tions of SmN and αFe were also visible. The energy dispersive spectra (EDS) for this alloy indicated that the average chemical composition was $\text{Sm}_{14.8}\text{Fe}_{80.5}\text{N}_{4.7}$. The higher nitrogen content in the material (4.7 at%) consistent with the

$\text{Sm}_2\text{Fe}_{17}\text{N}_3$ compound reflects the measurement of average N content for both the $\text{Sm}_2\text{Fe}_{17}\text{N}_3$ and the small inclusions of SmN phase. Dark field images revealed also the existence of thinner areas which could have arisen from dense inhomogeneities in the shock compacted samples.

We investigated the possibility of influencing the microstructure of magnets by the addition of Zn powder. For this experiment we used two $(\text{Sm}_{13.5}\text{Fe}_{86.5})_{1-x}\text{N}_x$ samples having different coercivities; low J_H (360 kA/m) — large grain milled ingot (particle and crystallite sizes both 3 μm) and high J_H (1900 kA/m) — nanocrystalline MA material (particle and crystallite sizes 50 μm and 30–60 nm, respectively). The addition of Zn to the powders before shock compaction resulted in a substantial increase of the coercivity for the former (up to 520 kA/m) and almost unchanged J_H for the latter (1930 kA/m). We relate the increase of J_H to better magnetic isolation of hard magnetic grains by a nonferromagnetic Zn-rich phase; however the coercivity of MA powder is apparently close to a maximum level for this composition and cannot be further improved.

Reversible processes and magnetic viscosity of nanocrystalline permanent magnets

D. R. Cornejo,^{a)} V. Villas-Boas, and F. P. Missell

Instituto de Física, Universidade de São Paulo, C. P. 66318, 05315-970 São Paulo S.P., Brazil

The accurate determination of the magnetic viscosity parameter S_v requires the calculation of a new parameter $\eta = (\partial M_{\text{rev}} / \partial M_{\text{irr}})_{H_i}$ which describes the dependence of reversible magnetization on irreversible magnetization. Measurements of the magnetic viscosity were performed at 300 K on the major demagnetization curves of two different nanocrystalline permanent magnetic materials: (i) melt-spun and flash-annealed $\text{Pr}_4\text{Fe}_{78}\text{B}_{18}$ and (ii) mechanically alloyed and heat-treated $\text{Sm}_{18}\text{Fe}_{33}\text{Co}_{49}$. We show that η is proportional to the intrinsic reversible susceptibility χ_{rev}^i , in good agreement with predictions of the moving Preisach model. Measurements of the reversible susceptibility were made in order to determine η . Experimental values of η are positive on the major demagnetization curve in both materials, resulting in substantial corrections to S_v near H_c .

I. INTRODUCTION

The problem of separating the magnetization M into reversible (M_{rev}) and irreversible (M_{irr}) components arises naturally in studies of the time dependence of M . In many materials, the time dependence of M in a constant field H can be described by the relation

$$M(t) = M_0 + S \ln(1 + t/t_0), \quad (1)$$

where M_0 and t_0 are constants and $S = S(D)$ is the magnetic viscosity, with D the demagnetization factor of the sample. Since S is sample shape dependent, another quantity S_v , the magnetic viscosity parameter, is more often used to characterize the time dependence of M . S_v is obtained in terms of S and the irreversible susceptibility χ_{irr} (also shape dependent) from the relation¹

$$S_v = S / \chi_{\text{irr}}. \quad (2)$$

However, χ_{irr} is a time-dependent quantity and care must be exercised in its determination. There are two common methods for obtaining χ_{irr} . In the DCD method, χ_{irr} is taken to be the derivative of the dc demagnetization curve that is obtained by measuring the remanence after applying progressively larger reverse fields after positive saturation. Alternatively, χ_{irr} can be determined as the difference of χ_{tot} and χ_{rev}^i , where χ_{tot} is the total susceptibility measured on the major hysteresis loop and the intrinsic reversible susceptibility χ_{rev}^i is measured by defining it as the mean slope of a small minor loop performed after determining the time dependence of M .

Schumann² has shown, however, that the two methods for determining χ_{irr} can result in substantially different values for this quantity. Crew *et al.*³ studied the resulting differences in S_v in terms of the Stoner–Wohlfarth model. They explained the differences in S_v in terms of a dependence of

M_{rev} on the configuration of domains in the material. This was expressed phenomenologically by Cammarano *et al.*⁴ using the equation

$$dM_{\text{rev}} = \chi_{\text{rev}}^i dH_i + \eta dM_{\text{irr}}, \quad (3)$$

where $H_i = H_{\text{ap}} - DM$ is the internal magnetic field. The quantities χ_{rev}^i and η are given by

$$\chi_{\text{rev}}^i = (\partial M_{\text{rev}} / \partial H_i)_{M_{\text{irr}}}$$

and

$$\eta = (\partial M_{\text{rev}} / \partial M_{\text{irr}})_{H_i}. \quad (4)$$

The parameter η measures the change in M_{rev} when the domain configuration, represented by M_{irr} , is changed. The relation between the reversible, irreversible, and total susceptibilities is then altered when $\eta \neq 0$:

$$dM_{\text{irr}} / dH_i = \chi_{\text{irr}} = (\chi_{\text{tot}} - \chi_{\text{rev}}^i) / (1 + \eta). \quad (5)$$

Using this relation, the relation between S and S_v becomes

$$\eta S_v = S(1 + D\chi_{\text{tot}} + \eta D\chi_{\text{irr}}) / (1 + \eta)\chi_{\text{irr}}. \quad (6)$$

This formalism has been used to discuss magnetic viscosity measurements in NdFeB ⁵ and in exchange-coupled $\text{Sm}_2\text{Fe}_{14}\text{Ga}_3\text{C}_2/\alpha\text{-Fe}$.⁶

In this article we consider two exchange-coupled materials with very different values of the reversible susceptibility: (i) melt-spun and flash-annealed $\text{Pr}_4\text{Fe}_{78}\text{B}_{18}$ and (ii) mechanically alloyed and heat-treated $\text{Sm}_{18}\text{Fe}_{33}\text{Co}_{49}$. For $\text{Pr}_4\text{Fe}_{78}\text{B}_{18}$, χ_{rev}^i is about 30% of χ_{tot} , while for $\text{Sm}_{18}\text{Fe}_{33}\text{Co}_{49}$, χ_{rev}^i is less than 5% of χ_{tot} . We derive a relation between η and χ_{rev}^i which is in agreement with predictions of the moving Preisach model.⁷ This relation allows us to determine η and ηS_v for both materials.

II. EXPERIMENT

Partially amorphous ribbons of $\text{Pr}_4\text{Fe}_{78}\text{B}_{18}$ were produced by melt spinning in He on a mild steel wheel. They were annealed for 20 s at $T = 640^\circ\text{C}$ by passing current

^{a)}Electronic mail: cornejo@macbeth.if.usp.br

FIG. 1. Magnetic viscosity S as a function of the internal magnetic field H_i for $\text{Pr}_4\text{Fe}_{78}\text{B}_{18}$ and $\text{Sm}_{18}\text{Fe}_{33}\text{Co}_{49}$.

through the sample, a process known as flash annealing.⁸ Previously, a Mössbauer analysis⁹ of flash-annealed $\text{Nd}_4\text{Fe}_{78}\text{B}_{18}$ showed 80% of the absorption to be due to magnetically soft Fe_3B . The flash-annealed ribbons of $\text{Pr}_4\text{Fe}_{78}\text{B}_{18}$ had $H_c = 4.0$ kOe and $M_r/M_s = 0.77$, thus showing enhanced-remanence behavior. Mechanical alloying of elementary Sm, Fe, and Co powders was carried out for 30 h with hardened steel balls in a hardened steel vial using a Fritsch Pulverisette-5 mill. As-milled powders composed of $\text{Sm}_{18}\text{Fe}_{33}\text{Co}_{49}$ were cold pressed into 3 mm diam cylinders and heated in vacuum for 15 min at 700 °C. The x-ray diffraction pattern indicated that a mixture of the hard magnetic phases $\text{Sm}(\text{Fe}, \text{Co})_5$ and $\text{Sm}(\text{Fe}, \text{Co})_7$ had been formed. This alloy also presents remanence enhancement ($M_r/M_s = 0.6$) and $H_c = 9.6$ kOe.

All magnetization measurements were carried out at room temperature using a vibrating sample magnetometer (VSM) mounted in a 90 kOe superconducting solenoid. Magnetization measurements for times between 20 and 300 s were fitted to Eq. (1) to determine the magnetic viscosity S . From the fits to Eq. (1) we typically obtained values of $t_0 \approx 1.5$ s. After the viscosity measurement, the magnetic field was varied by 200 Oe to measure χ_{rev}^i .

III. RESULTS AND DISCUSSION

The magnetic viscosity (S) results in both $\text{Pr}_4\text{Fe}_{78}\text{B}_{18}$ and $\text{Sm}_{18}\text{Fe}_{33}\text{Co}_{49}$ are presented in Fig. 1. In both materials we see that S presents a well-defined peak, centered at the coercive field H_c , the field at which χ_{irr} has its maximum value. Both sets of S values determined here are about the same order of magnitude as those encountered in two-phase $\text{Nd}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$ (Ref. 10) and exchange-coupled $\text{Sm}_2\text{Fe}_{14}\text{Ga}_3\text{C}_2/\alpha\text{-Fe}$.⁶ The authors of Ref. 10 observed a systematic decrease in S as the fraction of soft magnetic phase present was increased. Here the larger viscosity is associated with $\text{Pr}_4\text{Fe}_{78}\text{B}_{18}$, the material with more soft magnetic phase. A proper comparison, however, should involve materials containing the same phases. A systematic study of the behavior of S with the fraction of soft phase in SmFeCo will be presented elsewhere.

FIG. 2. The reversible susceptibility $4\pi\chi_{\text{rev}}^i$ and parameter η as a function of the internal field along the major hysteresis loop for (a) $\text{Pr}_4\text{Fe}_{78}\text{B}_{18}$ and (b) $\text{Sm}_{18}\text{Fe}_{33}\text{Co}_{49}$.

In order to determine S_v from S using Eq. (6), χ_{irr} was determined using Eq. (5) from the difference $\chi_{\text{tot}} - \chi_{\text{rev}}^i$, where χ_{tot} was derived from the major hysteresis loop and χ_{rev}^i was measured by defining it as the mean slope of a small minor loop performed after determining the time dependence of M . Measurements of $4\pi\chi_{\text{rev}}^i$ for the two samples are shown in Fig. 2. We note that the maximum value of χ_{rev}^i is about 30% of χ_{tot} for $\text{Pr}_4\text{Fe}_{78}\text{B}_{18}$. On the other hand, in $\text{Sm}_{18}\text{Fe}_{33}\text{Co}_{49}$, χ_{rev} is small, about 5% of χ_{tot} . For $\text{Sm}_{18}\text{Fe}_{33}\text{Co}_{49}$, we clearly observe a secondary peak in $4\pi\chi_{\text{rev}}^i$ at H_c . This occurs because χ_{rev}^i is a function of both H_i and M_{irr} , as will be discussed below. The larger peak is associated with the inversion of the soft phase, while the smaller peak reflects the inversion of the hard magnetic phase.

In order to determine η from the measured susceptibility, one must integrate the identity $(\partial\eta/\partial H_i)_{M_{\text{irr}}} = (\partial\chi_{\text{rev}}^i/\partial M_{\text{irr}})_{H_i}$. In Ref. 6, the authors apparently used $\delta M_{\text{irr}} = \chi_{\text{irr}} \Delta H_i$ to evaluate the right-hand side of that identity. But the right-hand side must be calculated with constant H_i . Using Eq. (4), the variation δM_{irr} for the H_i constant can be written as $\delta M_{\text{irr}} = \delta M_{\text{rev}}/\eta$, while the variation δH_i for the M_{irr} constant is given by $\delta H_i = \delta M_{\text{rev}}/\chi_{\text{rev}}^i$. The above identity then becomes

$$\chi_{\text{rev}}^i (\partial\eta/\partial M_{\text{rev}})_{M_{\text{irr}}} = \eta (\partial\chi_{\text{rev}}^i/\partial M_{\text{rev}})_{H_i}. \quad (7)$$

One can show that $(\delta M_{\text{rev}})_{M_{\text{irr}}} = (\delta M_{\text{rev}})_{H_i}$ in the limit that $\delta H_i \rightarrow 0$. Then, for $\delta H_i \rightarrow 0$, we have the relation $d\eta/\eta = d\chi_{\text{rev}}^i/\chi_{\text{rev}}^i$, which can be integrated to give

$$\eta = (\eta_0/\chi_{\text{rev}0}^i) \chi_{\text{rev}}^i. \quad (8)$$

Recently we applied the moving Preisach model to the problem of separating the magnetization into its reversible and irreversible components. We obtained⁷ a simple relation between η and the reversible susceptibility χ_{rev}^i : $\eta = k\chi_{\text{rev}}^i$, where k is the moving parameter of the moving Preisach model. In that model, the effective magnetic field acting on

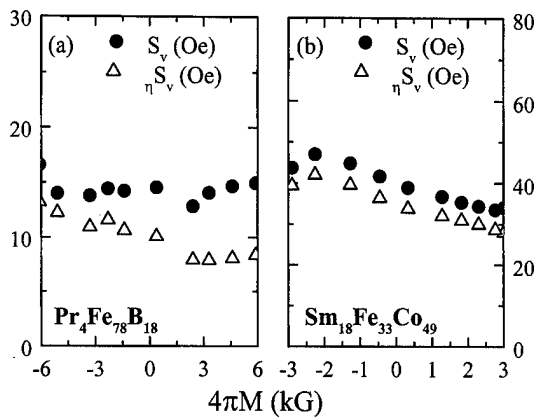

FIG. 3. The magnetic viscosity parameters S_v and ηS_v as a function of sample magnetization for (a) $\text{Pr}_4\text{Fe}_{78}\text{B}_{18}$ and (b) $\text{Sm}_{18}\text{Fe}_{33}\text{Co}_{49}$.

the system is $H = H_i + kM$, where H_i is the internal field and kM is a mean field term associated with the total magnetization M . This result suggests that the simple relation between η and χ_{rev}^i of Eq. (8) is, in fact, indicative of a collective behavior of the system.

There then remains the problem of choosing the initial values of η and χ_{rev}^i for use in Eq. (8). We take $\eta_0 = \eta(H_i = 0) = M_{R_{\text{rev}}} / (M_R - M_{R_{\text{rev}}})$, where $M_{R_{\text{rev}}}$ is the reversible magnetization at remanence ($H_i = 0$) and M_R is the total magnetization at remanence ($H_i = 0$). Our choice of η_0 would reduce to zero with $M_{R_{\text{rev}}} = 0$ at remanence. However, Cammarano *et al.*⁴ and Crew *et al.*³ have noted that M_{rev} is not a reversible function of the internal field as is generally assumed, but instead exhibits a small hysteresis. We have observed the same behavior in our materials. Thus $M_{R_{\text{rev}}}$ was determined by integrating χ_{rev}^i between $H_i = 0$ and the value of H_i corresponding to $M_{\text{rev}} = 0$. For $\text{Pr}_4\text{Fe}_{78}\text{B}_{18}$, we obtained $\eta_0 = 0.43 \pm 0.07$. Using $4\pi\chi_{\text{rev}_0}^i = (1.1 \pm 0.1) \text{ G/Oe}$, we obtained $k = (5 \pm 2) \text{ Oe/G}$. For $\text{Sm}_{18}\text{Fe}_{33}\text{Co}_{49}$, $\eta_0 = 0.07 \pm 0.01$. Using $4\pi\chi_{\text{rev}_0}^i = (0.020 \pm 0.005) \text{ G/Oe}$, we obtained $k = (40 \pm 30) \text{ Oe/G}$. We have not yet completed a moving Preisach model analysis of the materials studied in this article and, therefore, have not yet determined values of k for these materials. However, our Preisach analysis¹¹ of $\text{Sm}_{18}\text{Fe}_{11}\text{Co}_{71}$ yielded a moving parameter $k = 39 (4\pi M_s / H_c) \text{ Oe/G} \approx 18 \text{ Oe/G}$ for that material, which is in reasonable agreement with the value found here for $\text{Sm}_{18}\text{Fe}_{33}\text{Co}_{49}$. The calculated curves of η for the two materials are shown in Fig. 2.

The magnetic viscosity parameters S_v and ηS_v are shown as a function of the magnetization in Fig. 3 for $\text{Pr}_4\text{Fe}_{78}\text{B}_{18}$ and $\text{Sm}_{18}\text{Fe}_{33}\text{Co}_{49}$. For $\text{Pr}_4\text{Fe}_{78}\text{B}_{18}$, the correction to S_v due to η approaches 40% for positive values of M , while for $\text{Sm}_{18}\text{Fe}_{33}\text{Co}_{49}$ the correction is less than 20%. We note that smaller values of S_v and ηS_v are observed in $\text{Pr}_4\text{Fe}_{78}\text{B}_{18}$ which contains a large fraction of the soft mag-

netic phase Fe_3B . Insofar as S_v or ηS_v is related to the coercive field, then we would expect larger values for these quantities in $\text{Sm}_{18}\text{Fe}_{33}\text{Co}_{49}$ where H_c is larger.

Finally, we would like to comment on the origin of the hysteresis observed in M_{rev} . Using the relation $\eta = k\chi_{\text{rev}}^i$ in Eq. (3), we obtain

$$dM_{\text{rev}}(1 + k\chi_{\text{rev}}^i) = \chi_{\text{rev}}^i(dH_i + k dM). \quad (9)$$

We define the total internal field as $H_{it} = H_i + kM$ and the total reversible susceptibility as $\chi_{\text{rev}}^i = dM_{\text{rev}}/dH_{it} = \chi_{\text{rev}}^i / (1 + k\chi_{\text{rev}}^i)$. (This total internal field H_{it} is analogous to the effective field acting in the moving Preisach model.¹²) We note that χ_{rev}^i is a function of both H_i and M_{irr} and, therefore, is not reversible with regard to variations in H_i . On the other hand, χ_{rev}^i is a single-valued function of H_{it} and is completely reversible with regard to that field.⁷

IV. CONCLUSIONS

We have determined the magnetic viscosity parameter ηS_v for the nanocrystalline exchange-coupled alloys $\text{Pr}_4\text{Fe}_{78}\text{B}_{18}$ and $\text{Sm}_{18}\text{Fe}_{33}\text{Co}_{49}$, two materials for which the reversible contributions to the susceptibility are quite different. The dependence of the reversible magnetization on the magnetic domain structure (irreversible magnetization), as expressed through the parameter η , was determined and was used to correct S_v . In both cases the parameter η was determined from χ_{rev}^i using the relation $\eta = (\eta_0 / \chi_{\text{rev}_0}^i) \chi_{\text{rev}}^i$, which is similar in form to a relation derived previously⁷ within the context of the moving Preisach model: $\eta = k\chi_{\text{rev}}^i$. The systematic relationship, observed previously,¹⁰ between S and the amount of soft magnetic phase present could not be investigated here but will be considered in the SmFeCo system.

Magnetic properties of $RFe_{10.5}Mo_{1.5}C_x$ and their nitrides

Weihoa Mao,^{a)} Jinbo Yang, Benpei Cheng, and Yingchang Yang

Department of Physics, Peking University, Beijing 100871, People's Republic of China

$RFe_{10.5}Mo_{1.5}C_x$ ($R=Y, Nd, \text{ and } Dy; x=0-0.6$) have been successfully synthesized by arc melting, then followed by a gas-solid phase reaction to form $YFe_{10.5}Mo_{1.5}C_xN_y$. X-ray diffraction studies and thermomagnetic analysis show that all samples are of good single phase, and carbides and carbon nitrides remain the $ThMn_{12}$ -type structure. The addition of carbon atoms has an effect of improving the magnetic properties. Both Curie temperature and saturation magnetization are found to be increased with carbon concentration x in the $RFe_{10.5}Mo_{1.5}C_x$ series, and the carbon atoms also affect the magnetocrystalline anisotropy. The easy axial anisotropy of $NdFe_{10.5}Mo_{1.5}C_x$ and $DyFe_{10.5}Mo_{1.5}C_x$ is enhanced. As to the nitrides, the results indicate that $YFe_{10.5}Mo_{1.5}C_xN_y$ possess a higher Curie temperature and a larger saturation magnetization than $YFe_{10.5}Mo_{1.5}N_y$, which is of significance in the technical applications. © 1998 American Institute of Physics. [S0021-8979(98)21711-7]

I. INTRODUCTION

It has been found that the magnetic properties of the $ThMn_{12}$ -type compounds can be drastically improved by introducing of nitrogen or carbon atoms into the structure.¹⁻⁴ Owing to their excellent intrinsic magnetic properties, the nitrides and carbides of the $ThMn_{12}$ -type compounds have been regarded as promising candidates for permanent magnet applications. Unfortunately the nitrides or carbides prepared by gas-solid phase reaction are metastable compounds and they will disproportionate at temperature higher than 700 °C in general. Thus the conventional high-temperature powder metallurgy is not applicable to these materials.

Besides gas-solid phase reaction, there are many preparation techniques for carbides: (a) melting of constituents in arc or induction furnace,⁵⁻⁸ (b) synthesis from heavy hydrogencarbon compounds,⁹ and (c) solid-solid phase reaction.^{10,11} Above all, the advantage of carbides prepared by melting method is stability in high temperature. However, the single phase carbides with $ThMn_{12}$ -type structure are difficult to be synthesized by melting method, especially when the carbon content is larger than 0.3.

Yang *et al.* studied the effects of carbon on the structural and magnetic properties of $RTiFe_{10.75}C_{0.25}$.⁵ It was found that introducing the carbon atoms by arc melting have no effect on the Curie temperature, but the saturation magnetization is increased and the unit cell volume is decreased slightly with carbon content. They also reported that introducing the carbon atoms by arc melting increases the planar anisotropy for rare-earth ions with the negative second-order Stevens constant α_J such as Nd^{3+} and Dy^{3+} , and strengthens the axial anisotropy for those with positive α_J such as Sm^{3+} . The effect of arc-melting additions of carbon atoms is different from that of the interstitial nitrogen or carbon atoms introduced by the gas-solid phase reaction. Zhang *et al.*⁷ and Hu *et al.*⁸ published their results of neutron diffraction experiment carried out on $YFe_{11}TiC_{0.3}$ and $ErFe_{11}TiC_{0.25}$ prepared by arc melting. They found that all of the carbon atoms

introduced by arc-melting method occupy $8i$ sites, not the interstitial $2b$ sites. Hu *et al.* also studied the structure of $YFe_{10.5}Mo_{1.5}C_{0.3}$ prepared by arc melting, and he found it is different from $R(Fe,Ti)_{12}C_x$ compounds though all of the carbon atoms introduced by arc melting. He reported that only about 40% carbon atoms occupy $8i$ sites and the others occupy $2b$ sites in $YFe_{10.5}Mo_{1.5}C_{0.3}$. Since the location of arc melting introduced carbon atoms in the compounds $Y(Fe,Mo)_{12}C_x$ is different from that of $R(Fe,Ti)_{12}C_x$, the effect of carbon on the magnetic properties of $R(Fe,Mo)_{12}C_x$ would be different from that of $R(Fe,Ti)_{12}C_x$. But no systematic studies on magnetic properties of the $R(Fe,Mo)_{12}C_x$ prepared by arc-melting method are reported in literature. Since a part of carbon atoms occupy the $2b$ interstitial sites in the $RFe_{12-x}Mo_xC_y$ compounds, the interstitial modification might be significant if carbon content is large enough. It is imperative to study the magnetic properties of arc-melting $RFe_{12-x}Mo_xC_y$ with a high carbon content.

In this article, the magnetic properties of $RFe_{10.5}Mo_{1.5}C_x$ ($R=Y, Nd, \text{ and } Dy; x=0-0.6$) are reported. The combination effects of carbon and nitrogen in the $YFe_{10.5}Mo_{1.5}C_xN_y$ compounds are also investigated.

II. EXPERIMENTAL METHOD

$YFe_{10.5}Mo_{1.5}C_x$ ($x=0, 0.2, 0.4, 0.6$), $NdFe_{10.5}Mo_{1.5}C_x$ ($x=0, 0.2, 0.4$), and $DyFe_{10.5}Mo_{1.5}C_x$ ($x=0, 0.2, 0.4, 0.6$) were prepared by arc melting of 99.5% pure materials in a purified argon atmosphere. The carbon was introduced as Fe-C alloy. Carbon nitrides were prepared by passing purified nitrogen gas at atmospheric pressure over finely ground carbides powder samples (about 10–30 μm) at 400–600 °C for 2–6 h, then rapidly cooling to room temperature. The nitrogen content (y) of $YFe_{10.5}Mo_{1.5}C_xN_y$ was determined by weight increment upon nitrogenation. X-ray diffraction was used to determine the structure. The powder sample of cylindrical shape was aligned in a 20 kOe field in epoxy resin. Magnetic measurements are performed with a field of up to 20 kOe in a temperature range from 80 to 1000 K by using a vibrating sample magnetometer (VSM).

FIG. 1. The x-ray diffraction pattern of YFe_{10.5}Mo_{1.5}C_{0.6}.

III. RESULTS AND DISCUSSION

A. Crystallographic structure

According to the x-ray diffraction studies and thermo-magnetic analysis, all samples are found to remain the ThMn₁₂-type tetragonal structure, and, no α -Fe phase is observed. Figure 1 illustrates the x-ray diffraction patterns of YFe_{10.5}Mo_{1.5}C_{0.6}. The lattice parameters are listed in Table I. The cell volume increases with the carbon content, which is different from the case of R(Fe,Ti)₁₂C_x.⁵ These results suggest that a significant part of carbon atoms are introduced into the interstitial sites.

B. Curie temperature and saturation magnetization

The Curie temperature (T_c) and saturation magnetization (σ_s) of RFe_{10.5}Mo_{1.5}C_x (R=Y, Nd, and Dy) are indicated in Table I. The carbon atoms have an effect of increasing both Curie temperature and saturation magnetization. Since yttrium is nonmagnetic, the moment of yttrium compounds represents that of the Fe sublattice. The carbon increases the average magnetization of Fe atoms in the lattice.

FIG. 2. Average Fe moments of YFe_{10.5}Mo_{1.5}C_x vs carbon content (the solid dot is the average Fe moment of YFe_{10.5}Mo_{1.5}N).

The variation of average Fe magnetic moments as a function the carbon content (x) is illustrated in Fig. 2. The results could be extrapolated to $x=1$, and at that point, average Fe moment is about $1.65\mu_B$ at room temperature. The average Fe moment in the YFe_{10.5}Mo_{1.5}N is $1.60\mu_B$ (the solid dot in Fig. 2). It indicates that the arc melting introduced carbon atoms have a similar effect on the average Fe magnetic moments to that of nitrogen atoms.

C. Magnetocrystalline anisotropy

The anisotropy field H_A is calculated by using Sucksmith–Thompson method.¹² The results are listed in Table I.

The carbon effect on the magnetocrystalline anisotropy of the Fe sublattice can be deduced from the yttrium compounds YFe_{10.5}Mo_{1.5}C_x. There is a slight decrease trend with the carbon content, which is similar to the interstitial nitrogen effect.

The arc melting introduced carbon atoms also have a drastic effect on the magnetocrystalline anisotropy of the rare-earth sublattice. The H_A of RFe_{10.5}Mo_{1.5}C_x (R=Nd and

FIG. 3. Magnetization curves of $\text{DyFe}_{10.5}\text{Mo}_{1.5}\text{C}_x$ ($x=0$ and 0.6) at 300 K , parallel and perpendicular to the orientation direction.

Dy) increases with the carbon content (see Table I). The easy axial anisotropy of $\text{DyFe}_{10.5}\text{Mo}_{1.5}\text{C}_x$ is significantly enhanced, as shown in Fig. 3, in which the magnetization curves of $\text{DyFe}_{10.5}\text{Mo}_{1.5}\text{C}_x$ ($x=0$ and 0.6) are illustrated. In the case of $\text{R}=\text{Nd}$, the similar results are observed. A spin reorientation occurs in $\text{NdFe}_{10.5}\text{Mo}_{1.5}\text{C}_x$, when $x=0$ and 0.2 . The spin reorientation results from the competition between the easy-plane anisotropy of the Nd^{3+} sublattice and the easy-axial anisotropy of Fe sublattice. The spin reorientation temperature (SRT) of $\text{NdFe}_{10.5}\text{Mo}_{1.5}$ is 170 K , while it decreases to 135 K with $\text{NdFe}_{10.5}\text{Mo}_{1.5}\text{C}_{0.2}$. In the case of $\text{NdFe}_{10.5}\text{Mo}_{1.5}\text{C}_{0.4}$, no spin reorientation is detected above 80 K . It could be concluded that the addition of carbon leads to a change in the anisotropy of the Nd^{3+} ions, which have a tendency to transform their easy magnetization direction from easy plane to easy axis.

As to the magnetocrystalline anisotropy, the effect of the arc melting introduced carbon atoms of the $\text{RFe}_{10.5}\text{Mo}_{1.5}\text{C}_x$ is similar to that of interstitial nitrogen and carbon atoms which are introduced by gas-solid phase reaction. These results indicate that there is a significant part of carbon atoms introduced into the interstitial $2b$ site. When the carbon atoms occupy $2b$ site, they could change the second-order crystal-field coefficient A_{20} from negative to positive. As a result, the easy magnetization direction of rare-earth ions with the negative second-order Stevens constant α_J such as Nd^{3+} and Dy^{3+} may change from easy plane to easy axis.

D. Combination effect of carbon and nitrogen

After nitrogenation, the x-ray diffraction studies and thermomagnetic analysis indicate that all nitrides of $\text{YFe}_{10.5}\text{Mo}_{1.5}\text{C}_x$ remain ThMn_{12} -type structure and no α -Fe phase is observed. The lattice parameters and unit cell volume are listed in Table I.

The Curie temperature and saturation magnetization of carbon nitrides increase rapidly. This is due to the effect of

interstitial modification. It should be noted that the Curie temperature and saturation magnetization of carbon nitrides are larger than those of carbon free nitride ($x=0$). The saturation magnetization of carbon nitrides is larger than simple nitride by 3–4%. It proves a method to enhance the saturation magnetization of nitrides, which is of significance in the technical applications.

The nitrogen content (y) in the $\text{YFe}_{10.5}\text{Mo}_{1.5}\text{C}_x\text{N}_y$ is listed in Table I. The average error of y is 0.05 . It is very interesting that the nitrogen contents decrease with the increasing of carbon content and their sums ($x+y$) approximate 1. In order to characterize carbon location in the $\text{R}(\text{Fe}, \text{Mo})_{12}$ compounds and its effect on the local magnetic moments, the neutron diffraction experiments with the relative carbides are in progress.

IV. CONCLUSION

In conclusion, the carbon atom introduced by arc melting not only have an effect of increasing both Curie temperature and saturation magnetization of $\text{R}(\text{Fe}, \text{Mo})_{12}$ compounds, but also give rise to an change in the magnetocrystalline anisotropy. Their effects are similar to those of the nitrogen or carbon atoms introduced by gas-solid phase reaction, but the arc-melting carbides are much more stable in the high temperature than those prepared by gas-solid phase reaction.

Effects of nitrogen contents and substrate temperatures to the microstructure and magnetic properties of the FeCoN films have been investigated. According to the TEM and x-ray Scherrer's equation analyses, we found that the grain size of films with substrate temperature below 200 °C is roughly about 13 nm, however, it increases very fast for films with substrate temperature above 300 °C. N content in the films is saturated to 30 at. %, as N_2 flow ratio $N_2/(Ar+N_2)$ is higher than 5 vol. %. From the magnetization studies, we have found that the saturation magnetization $4\pi M_s$ of the optimum samples (with the substrate temperature near 200 °C) is 23.9 kG. The improvement of the magnetic properties is attributed to the combination of α -Fe with N to form the high magnetic moment FeN phases. © 1998 American Institute of Physics. [S0021-8979(98)35011-2]

I. INTRODUCTION

A soft magnetic film with high saturation magnetization $4\pi M_s$ is required for use in a high-density magnetic recording head. Recently, extensive efforts have been made to improve the soft magnetic properties of Fe-based films.¹⁻⁷ According to the Pauling-Slater curve, Fe-Co alloys have the highest magnetization of iron alloy. Takahashi *et al.*⁸ prepared FeCo nitride film onto a polyimide substrate by ion-assisted normally vapor deposition method. They found that the film was columnar structure with large grains of about 500 Å and maximum $4\pi M_s$ occurred at the Co content of about 32 at. %. Their films have large perpendicular magnetic anisotropy and N content of the film is unknown. On the other hand, Liao⁹ reported that electrodeposited Fe₉₀Co₁₀ films show a high $4\pi M_s$ value of 19 kG and good soft magnetic properties. Recently, Nakagawa *et al.*¹⁰ examined the FeCoN and FeCoTaN films which prepared by facing targets sputtering with N_2 +Kr mixture gas. They found that $4\pi M_s$ of the film was decreased with increasing N_2 partial pressure. Pure Fe₉₀Co₁₀ alloy film has an extremely large $4\pi M_s$ of about 24 kG. In this report, we investigate the effect of substrate temperature and N content on the magnetic properties and microstructures of sputtered FeCoN films.

II. EXPERIMENT

(Fe_{0.9}Co_{0.1})_{100-x}N_x films with $x=0-30$ were prepared on a precleaned glass substrate by reactive RF magnetron sputtering in N_2 and Ar mixed atmosphere. The flow ratio of nitrogen to argon and nitrogen, i.e., $N_2/(Ar+N_2)$, during sputtering was varied between 0 and 10 vol. %. The substrate temperature was varied between 25 and 400 °C. Composite

target consisting of pure Fe disk overlaid with Co pieces was used in this experiment. The base pressure in the system with a turbo pump was 1×10^{-6} Torr, and after the high purity Ar- N_2 mixed gas was introduced, sputtering pressure was 1×10^{-3} Torr. Thickness of the films was about 200 nm.

Structure and grain size of the films were determined by using x-ray diffractometer (XRD). Thickness of the films was measured by a Sloan DEKTAK-3-0305ST α -step profilometer. Magnetic properties of the films were measured with vibrating sample magnetometer (VSM) at room temperature with maximum applied field of 12 kOe. Composition, N content, and homogeneity of the films were determined by depth profiling analysis of Auger electron spectroscopy (AES).

III. RESULTS AND DISCUSSION

Figure 1 shows the N contents in pure Fe, Co, and Fe₉₀Co₁₀ films as a function of N_2 flow ratio during sputtering, i.e., $(N_2/Ar+N_2) \times 100\%$, with the substrate temperature T_s kept at 25 °C. It can be seen that N content in the films increases dramatically with increasing N_2 flow ratio when N_2 flow ratio is lower than 5 vol. %. This is because N atoms can easily occupy interstitial sites of crystal lattice during deposition as N_2 flow ratio is lower than 5 vol. %. N content in the film is saturated as N_2 flow ratio is higher than 5 vol. % for all films. This is due to that all interstitial sites of crystal lattices in the film are occupied. Saturated N content of Fe film is about 32 at. % which is equal to the N content of ζ -Fe₂N phase.¹¹ ζ -Fe₂N phase is nonmagnetic and has maximum equilibrium N content in Fe-N binary system.¹² The maximum N contents of Fe₉₀Co₁₀ and Co films are 30 and 23 at. %, respectively. Figure 2 presents a

FIG. 1. Variation of N content with N₂ flow ratio of Fe, Fe₉₀Co₁₀ and Co films. The substrate temperature is kept at 25 °C.

typical depth profile of a FeCoN film analyzed by Auger electron spectroscopy (AES). We can see that the composition of this film is approximately (Fe_{0.9}Co_{0.1})₇₀N₃₀. It is calibrated by a standard of bulk Fe₅₀Co₅₀ alloy. Because the films were exposed to air prior to AES analysis, near the surface of the films, O and C were always observed as shown in Fig. 2.

Typical microstructure of the (Fe_{0.9}Co_{0.1})_{100-x}N_x films is shown in Fig. 3. Figure 3(a) is a TEM photograph of the (Fe_{0.9}Co_{0.1})₇₇N₂₃ film with substrate temperature of 25 °C. We can see that the film has a nanocrystalline structure and its average grain size is about 13 nm. In Fig. 3(b), from the diffraction lines of the electron diffraction pattern of this film, we noticed that ϵ -Fe₂₋₃N, Co₂N, γ' -Fe₄N, and ζ -Fe₂N phases are included.

Figure 4 shows the saturation magnetization $4\pi M_s$ and coercivity H_c as a function of N content in (Fe_{0.9}Co_{0.1})_{100-x}N_x films with its substrate temperature at 25 °C. It is clear that $4\pi M_s$, and both in-plane coercivity $H_{c\parallel}$ and perpendicular coercivity $H_{c\perp}$ of the films increase slowly from 22 to 22.8 kG, 12 to 18 Oe, and 22 to 30 Oe, respectively, for N less than roughly 13 at. %. However,

FIG. 2. Auger depth profile of a (Fe_{0.9}Co_{0.1})₇₀N₃₀ film.

FIG. 3. TEM micrograph and electron diffraction pattern of (Fe_{0.9}Co_{0.1})₇₇N₂₃ film with $T_s = 25$ °C. (a) is the microstructure of planar section and (b) is the corresponding electron diffraction pattern.

$4\pi M_s$ decreases and both H_c 's increase rapidly as N content is larger than 13 at. %. When N content is approached to 30 at. %, both H_c increase to about 150 Oe and $4\pi M_s$ decreases to about 2 kG due to the formation of ζ -Fe₂N phase in the film. The perpendicular coercivity $H_{c\perp}$ is slightly higher than that of the in-plane coercivity $H_{c\parallel}$. This indicates that the film is almost magnetic isotropy as substrate temperature is kept at 25 °C.

Figure 5 shows the relation between $4\pi M_s$, $H_{c\parallel}$, $H_{c\perp}$ and substrate temperature T_s of the (Fe_{0.9}Co_{0.1})_{100-x}N_x films prepared with the flow ratio of N₂ at 1 vol. % during sputtering. According to the AES analysis, the N content of the

FIG. 4. Effect of N content on the $4\pi M_s$, $H_{c\parallel}$, and $H_{c\perp}$ of (Fe_{0.9}Co_{0.1})_{100-x}N_x films. The substrate temperature is kept at 25 °C.

FIG. 5. The change of $4\pi M_s$, H_{cL} , and H_{cH} against T_s for $(\text{Fe}_{0.9}\text{Co}_{0.1})_{100-x}\text{N}_x$ films. N_2 flow ratio is 1 vol. % during sputtering.

film was found to decrease from 13 at. % for $T_s = 25^\circ\text{C}$ to 10 at. % for $T_s = 100^\circ\text{C}$, 8 at. % for $T_s = 200^\circ\text{C}$, and 3 at. % for $T_s = 400^\circ\text{C}$. It can be seen that H_{cL} increases monotonously from 25 to 165 Oe when T_s increasing from 25 to 400°C , but H_{cH} of the film is increased rapidly from 25 to 530 Oe. It is obvious that magnetic easy axis is in the film plane, as T_s is higher than 25°C . The increasing of coercivities with T_s is owing to that N content of the film is decreased with increasing T_s . From the x-ray diffraction patterns study of the films at various T_s , we found that the amount of high coercivity FeCo phase is increased with T_s . For example, Fig. 6 shows curves (a) to (c) with their substrate temperatures at 25, 100, and 200°C , respectively. When T_s is higher than 300°C , only the FeCo peak can be detected by x-ray diffractometer. According to the x-ray Scherrer's equation analysis from the diffraction peak of FeCo(100), we found that the grain size of the films with substrate temperature below 200°C is roughly about 13 nm, however, it increases very fast for films with substrate temperature above 300°C .

The $4\pi M_s$ in Fig. 5 shows a minimum value of 21.7 kG around 100°C , and a maximum value of 24 kG at $T_s \approx 200^\circ\text{C}$. Comparing with the x-ray diffraction peaks of Figs. 6(a), 6(b), and 6(c), we can see that these films all contain high moment FeCo and $\alpha' - \text{Fe}_{6-10}\text{N}$ phases.¹³ From this point of view, variation of the $4\pi M_s$ of film with T_s is due to the change of N content in the film, i.e., amounts of various FeN, FeCo, CoN, α -Fe phases in the film are changed.

IV. CONCLUSIONS

In conclusion, effects of nitrogen contents and substrate temperatures to the microstructure and magnetic properties of the $(\text{Fe}_{0.9}\text{Co}_{0.1})_{100-x}\text{N}_x$ films with $x=0-30$ films have been investigated. TEM observation found that they have nanocrystalline structure. When N content of the film is

FIG. 6. X-ray diffraction patterns of various $(\text{Fe}_{0.9}\text{Co}_{0.1})_{100-x}\text{N}_x$ films. N_2 flow ratio is 1 vol. % during sputtering and substrate temperatures are (a) $T_s = 25^\circ\text{C}$, (b) $T_s = 100^\circ\text{C}$, and (c) $T_s = 200^\circ\text{C}$.

lower than 13 at. %, it contains high moment $\alpha' - \text{Fe}_{6-10}\text{N}$, FeCo, and $\gamma' - \text{Fe}_4\text{N}$ phases. The $(\text{Fe}_{0.9}\text{Co}_{0.1})_{92}\text{N}_8$ film which prepared at substrate temperature of about 200°C and N_2 flow ratio of 1 vol. % has maximum $4\pi M_s$ of 23.9 kG. As N content of the film is higher than 20 at. %, $4\pi M_s$ of the film decreases rapidly due to the formation of nonmagnetic $\zeta - \text{Fe}_2\text{N}$ phase in the film.

Fe–Zr–N thin films were deposited in an argon and nitrogen mixed atmosphere using a rf magnetron reactive sputtering apparatus at room temperature. The x-ray diffraction pattern of the $\text{Fe}_{76}\text{Zr}_{8}\text{N}_{16}$ thin film obtained at room temperature indicates that the as-sputtered film consists of amorphous and crystalline phases. The mixed structure of the sample was also confirmed by the temperature dependence of the saturation magnetic flux density. The as-sputtered film exhibited soft magnetic properties with a saturation magnetic flux density of 1.1 T and effective permeability of 1400 or more at 1 MHz. The film also showed good thermal stability, sustaining the effective permeability of 3000 at temperatures up to 550 °C. The film annealed in a magnetic field of 500 Oe at 450 °C showed a permeability of 2200 or more up to 40 MHz. The conventional Mössbauer spectrum of the kapton substrate sample obtained at room temperature could be fitted by a mixture of three kinds of six-line hyperfine splittings. © 1998 American Institute of Physics. [S0021-8979(98)16711-7]

I. INTRODUCTION

Recently various investigations have been performed on the development of soft magnetic materials with high saturation magnetic flux densities that would be useful for high density magnetic recording systems.^{1–3} High saturation magnetic flux densities and excellent soft magnetic properties at high frequencies are essential for magnetic recording head materials. To reduce the magnetocrystalline anisotropy of Fe, most of these investigations on Fe-based alloy films are concentrated on research to reduce the grain size of magnetically coupled α -Fe. It is reported that the addition of a B, N, or C element to Fe-based alloy reduces the grain size, but high temperature treatments often prevent the fine grain size to be maintained.^{4–6}

Fe–M–N (M=Zr, Hf, Ta, Nb) ternary systems⁷ also exhibit excellent soft magnetic properties even after heat treatments above 550 °C. The Fe–Zr–N ternary alloy, especially, has merits for practical use, such as low material cost and a wide range of composition in which desirable soft magnetic properties can be achieved.

In this work, Fe–Zr–N thin films were made using a rf magnetron sputtering technique, and the dependence of the magnetic properties of the samples, such as the saturation magnetic flux density and the effective permeability, on the annealing temperature were examined. In order to investigate the thermal stability of the film, the temperature dependence of the saturation magnetic flux density of the sample was studied. Also, the magnetic hyperfine field of Fe particles in the sample was examined by conventional Mössbauer spectroscopy.

II. EXPERIMENT

Fe–Zr–N thin films were deposited on various substrates (Corning glass No. 7059, a Si wafer, and kapton) in an argon and nitrogen mixed atmosphere using a rf magnetron reactive sputtering apparatus at room temperature. In order to avoid oxidation of the films during annealing, the silicon dioxide film was coated with a thickness of 1000 Å. The as-sputtered film was annealed at 200–700 °C for 30 min in a nitrogen atmosphere. The background pressure was lower than 7.0×10^{-7} Torr. A mixture of argon and nitrogen with a purity 99.999% was used as the sputtering gas. The deposition gas pressure was fixed at 6 mTorr, and the partial pres-

FIG. 1. The x-ray diffraction pattern of the as-sputtered $\text{Fe}_{76}\text{Zr}_{8}\text{N}_{16}$ thin film.

FIG. 2. Thermomagnetic diagram of the $\text{Fe}_{76}\text{Zr}_8\text{N}_{16}$ thin films.

sure of the nitrogen was 5%. The thickness and the composition of the films were about 900 Å and $\text{Fe}_{76}\text{Zr}_8\text{N}_{16}$, respectively.

The composition of the sample was examined by electron probe microanalysis (EPMA), Auger electron spectroscopy (AES), and Rutherford backscattering spectroscopy (RBS). The crystallographic characteristics and the microstructure of the films were analyzed by x-ray diffractometry (XRD) and scanning electron microscope (SEM), respectively. The saturation magnetic flux density, the coercive force, and the thermomagnetic properties were measured with a vibrating sample magnetometer. Conventional Mössbauer spectroscopy for ^{57}Fe for as-sputtered film was carried out using an electron detector of gas (He 90%– CH_4 10%) flow type at room temperature.

III. RESULTS AND DISCUSSIONS

The x-ray diffraction pattern of the as-sputtered $\text{Fe}_{76}\text{Zr}_8\text{N}_{16}$ thin film obtained at room temperature is shown in Fig. 1. The full width at half maximum of the peak appeared at $2\theta=45.5^\circ$ is about 2.5° .

Figure 2 represents the saturation magnetic flux densities B_s as a function of temperature for the $\text{Fe}_{76}\text{Zr}_8\text{N}_{16}$ thin films. The saturation magnetic flux density decreases slowly with increasing temperature up to 240 °C, and it decreases significantly in and around 280 °C, which is considered to be Curie temperature of the amorphous phase. And then, the saturation magnetic flux density increases abruptly at 310 °C. This phenomenon is possibly due to the crystallization of the amorphous film. Finally, it behaves like a typical ferromagnetic material in the range above 450 °C, and the value approaches zero at 710 °C, which is the Curie temperature for $\alpha\text{-Fe}$.

Figure 3 shows the saturation magnetic flux densities B_s and the effective permeabilities μ_{eff} as a function of annealing temperature for the $\text{Fe}_{76}\text{Zr}_8\text{N}_{16}$ thin film. The saturation magnetic flux density of the film increases slightly with increasing annealing temperature up to 350 °C, and then increases abruptly at 350 °C. This effect is associated with the increased phase transition from the amorphous to the crystal state with annealing temperature. We suppose therefore that the x-ray diffraction pattern shown in Fig. 1 indicates a com-

FIG. 3. Dependence of saturation magnetic flux density (B_s) and effective permeability (μ_{eff}) (at 1 MHz) on the annealing temperature of the $\text{Fe}_{76}\text{Zr}_8\text{N}_{16}$ thin films.

bination of these states. The phase transition appears to decrease with annealing temperature in the range above 450 °C. The effective permeability increases slightly with increasing annealing temperature up to 350 °C with a maximum value of 4800, but decreases rapidly with increasing annealing temperature in the range above 450 °C, while maintaining the effective permeability of 3000 at temperatures up to 550 °C. This result indicates that the $\text{Fe}_{76}\text{Zr}_8\text{N}_{16}$ thin film has good thermal stability up to 550 °C.

The coercive force of the as-sputtered film was 0.4 Oe, and it decreases slowly with increasing annealing temperature in the range up to 550 °C. It has the minimum value of 0.2 Oe at 550 °C and increases abruptly above 600 °C.

SEM micrographs show that the as-sputtered film has an amorphouslike structure, and that the sample annealed at 450 °C is slightly crystallized. With further annealing above 650 °C, a columnar structure was formed, possibly resulting in the observed abrupt increase in coercive force of the annealed sample.

Figure 4 represents the effective permeabilities of the $\text{Fe}_{76}\text{Zr}_8\text{N}_{16}$ thin films as a function of frequency. The sample annealed (in no field) at 450 °C has a permeability of 4800 at 1 MHz and 4000 at 5 MHz, but it decreases rapidly with increasing frequency in the range above 5 MHz. However,

FIG. 4. Frequency characteristics of effective permeability (μ_{eff}) for the $\text{Fe}_{76}\text{Zr}_8\text{N}_{16}$ thin films annealed at 450 °C.

FIG. 5. Mössbauer spectrum at room temperature for the as-deposited $\text{Fe}_{76}\text{Zr}_8\text{N}_{16}$ thin film.

the film annealed in a 500 Oe magnetic field at 450 °C, perpendicular to the film plane, has a permeability of 2200 or more up to 40 MHz. This is due to a decrease of the in-plane uniaxial anisotropy of the film during annealing in the magnetic field.

The Mössbauer spectrum at room temperature for the kapton substrate sample is shown in Fig. 5. This spectrum was fitted by a sum of three kinds of six-line hyperfine splittings with fairly good quality. The three kinds of iron sites (I), (II), and (III) have values of magnetic hyperfine fields (H_i) of 331, 321, and 276 kOe, respectively. The Fe(I) state with a hyperfine field of 331 kOe corresponds to α -Fe and the Fe(II) state with $H_i = 321$ kOe corresponds to iron atoms surrounded by interstitial nitrogen atoms. On the other hand, the Fe(III) iron site with 276 kOe seems to correspond to iron atoms surrounded by zirconium atoms. The substitutional zirconium atoms will interact chemically with iron atoms, which leads to a decrease in the saturation magnetic flux

density of α -Fe, i.e., the decrease in H_i of iron atoms in α -Fe. The resonant areas of each iron site, calculated from the intensity of each subspectrum, were almost same.

IV. CONCLUSION

In this article, the influence of annealing temperature on the structure and magnetic properties of a $\text{Fe}_{76}\text{Zr}_8\text{N}_{16}$ thin film made using a rf magnetron sputtering at room temperature was studied. The as-sputtered film exhibited soft magnetic properties with a saturation magnetic flux density of 1.1 T and an effective permeability of 1400 or more at 1 MHz. The film also showed good thermal stability by sustaining the effective permeability of 3000 up to 550 °C. The film annealed in a magnetic field of 500 Oe at 450 °C showed permeability of 2200 or more up to 40 MHz. The Mössbauer spectrum at room temperature indicated that some of the nitrogen and zirconium atoms are incorporated into α -Fe interstitially and substitutionally, respectively.

Fe-Nb-B-N films with good soft magnetic properties were fabricated by Ar+N₂ reactive sputtering. The quaternary films have better soft magnetic properties than that of Fe-Nb-B films. The best magnetic properties are saturation magnetization of 16.5 kG, coercivity of 0.13 Oe and effective permeability of about 5000 up to 10 MHz. It was observed by transmission electron microscopy that the Fe-Nb-B-N thin film annealed at 590 °C consisted of three phases: a fine α -Fe phase whose grain size is around 7 nm, a Nb-B rich amorphous phase and NbN precipitates with the size of less than 3 nm. The fine grained α -Fe structure, together with finely dispersed NbN precipitates and the amorphous boundary phase are considered to be a main factor for the good magnetic properties. © 1998 American Institute of Physics. I. INTRODUCTION

Recently, Fe-Nb-B thin films¹ with nanometer-scale grain size were reported to exhibit good soft magnetic properties. The microstructures of Fe-Nb-B film are composed of a major part of α -Fe grains and a small part of residual intergranular amorphous layer. The nanoscale α -Fe grains contain a small amount of Nb and B elements, which results in the small magnetostriction. The intergranular amorphous phase has high T_c resulting from a larger amount of Nb and B elements in the phase, which cause the strong magnetic exchange coupling of bcc grains. Nitrogen addition in Fe-Hf-C thin films was known to be an effective method to obtain good soft magnetic properties, which result from α -Fe phase refinement by Hf(C,N) precipitates.² Thus, it is expected that good soft magnetic properties can be obtained by means of the nitrogen addition in Fe-Nb-B system.

In this work, we studied the effect of nitrogen addition in Fe-Nb-B system on soft magnetic properties such as high saturation magnetization and high effective permeability in high frequency ranges.

II. EXPERIMENTAL PROCEDURE

Fe-Nb-B-N films were fabricated in Ar+N₂ plasma by a rf magnetron sputtering apparatus. The target consisted of an Fe-10 at. % B disk with small pieces of Nb. The partial pressure of N₂ gas was controlled in the range of 0%-4% keeping the total gas pressure of 2 mTorr constant. The films which were deposited onto Corning 7059 glass substrates were disk shaped with 10 mm diameter and about 1 μ m thickness. The composition of film was analyzed by Auger electron spectroscopy (AES). The films were annealed at 450–700 °C for 1 h in vacuum of 10⁻⁶ Torr. The saturation magnetization ($4\pi M_s$) and coercivity (H_c) were measured using a vibrating sample magnetometer (VSM). The effective permeability (μ_{eff}) was measured at the frequency range

of 0.5–100 MHz by a figure-8 coil method. The electrical resistivity (ρ) was determined by a four point probe method. The microstructures were investigated by x-ray diffractometry (XRD) using Cu-K α radiation and transmission electron microscopy (TEM) combined with nanobeam electron diffraction.

III. RESULTS AND DISCUSSION

Figure 1 shows the compositional diagrams for μ_{eff} and $4\pi M_s$ of Fe-Nb-B-N films annealed at optimum tempera-

FIG. 1. Compositional diagrams of effective permeability (μ_{eff}) and saturation magnetization ($4\pi M_s$) for Fe-Nb-B-N films annealed at optimum temperatures for 1 h.

FIG. 2. The changes of effective permeability (μ_{eff}) according to rf input power for $\text{Fe}_{70}\text{Nb}_{14}\text{B}_{11}\text{N}_5$ film with annealing temperature.

tures, obtained from systematic heat treatment experiments. The Fe-Nb-B-N films exhibited high μ_{eff} of more than 4000 and $4\pi M_s$ of above 16 kG in the composition range where the Fe, Nb, and N content are 70–72, 13–14, and 5–6 at. %, respectively. It was investigated that $\text{Fe}_{70}\text{Nb}_{14}\text{B}_{11}\text{N}_5$ film was the optimum composition for the best magnetic properties in a Fe-Nb-B-N system.

Figure 2 shows the changes of μ_{eff} at 10 MHz as a function of annealing temperature at various rf input powers. At the input power of 250 W, μ_{eff} is significantly high as 5000 compared to the other conditions. From the results of Fig. 2, it was considered that the film deposited at 250 W and annealed at 590 °C was the optimum condition for the best magnetic properties in $\text{Fe}_{70}\text{Nb}_{14}\text{B}_{11}\text{N}_5$ film.

The dependence of annealing temperature (T_a) on magnetic properties for $\text{Fe}_{70}\text{Nb}_{14}\text{B}_{11}\text{N}_5$ film were studied. Figure 3 shows the changes of $4\pi M_s$, H_c , and μ_{eff} at 10 MHz for $\text{Fe}_{70}\text{Nb}_{14}\text{B}_{11}\text{N}_5$ film as a function of annealing temperature. $4\pi M_s$ was small, below 480 °C, but it increased drastically with increasing T_a and showed the maximum of 16.5 kG at 590 °C. The rapid increase of $4\pi M_s$ is due to the structural change from the amorphous phase with low M_s showing an Invar effect to the α -Fe phase with high M_s . The lowest H_c in the crystallized state was 0.13 Oe at 590 °C, and it increased rapidly above 600 °C. The μ_{eff} at 10 MHz increased with increasing annealing temperature and reached a maximum value of 5000 at 590 °C. With the further increase of annealing temperature, effective permeability decreased rapidly. This behavior of μ_{eff} vs T_a in the present work is similar to that of annealed nanocrystalline alloys reported elsewhere.^{3,4}

Figure 4 shows the frequency dependence of the effective permeability (μ') and μ'' for $\text{Fe}_{70}\text{Nb}_{14}\text{B}_{11}\text{N}_5$ film annealed at 590 °C. Higher permeabilities of 5000 were maintained up to 10 MHz.

FIG. 3. The changes of saturation magnetization ($4\pi M_s$), coercivity (H_c), and effective permeability (μ_{eff}) for $\text{Fe}_{70}\text{Nb}_{14}\text{B}_{11}\text{N}_5$ film with annealing temperature.

The above-mentioned magnetic properties of Fe-Nb-B-N thin film are expected to be related to some microstructural modifications. Figure 5 shows the variation of x-ray diffraction patterns with annealing temperatures for $\text{Fe}_{70}\text{Nb}_{14}\text{B}_{11}\text{N}_5$ films. Up to 480 °C, typical broad peaks suggest the amorphous state appeared. However, an α -Fe (110) main peak sharpened at 530 °C, indicating the occurrence of crystallization. When T_a reached 590 °C, clear (110), (200), and (211) peaks of the α -Fe phase appeared. From this result, it was concluded that the increase of μ_{eff} and $4\pi M_s$,

FIG. 4. Frequency dependence of effective permeability (μ') and μ'') for $\text{Fe}_{70}\text{Nb}_{14}\text{B}_{11}\text{N}_5$ film annealed at optimum annealing temperature.

FIG. 5. The variations of XRD patterns for $\text{Fe}_{70}\text{Nb}_{14}\text{B}_{11}\text{N}_5$ film as a function of annealing temperature.

and the decrease of H_c in the T_a range of 500–600 °C resulted from the formation of α -Fe phase. And the variations of α -Fe grain size for $\text{Fe}_{70}\text{Nb}_{14}\text{B}_{11}\text{N}_5$ film with annealing temperature were shown in Table I. These values were calculated by the Scherrer's formula using XRD main peaks shown in Fig. 5.

In order to investigate the effect of nitrogen on microstructure of the thin film, TEM images (bright field, diffraction pattern, α -Fe dark field and NbN dark field) of $\text{Fe}_{70}\text{Nb}_{14}\text{B}_{11}\text{N}_5$ film annealed at 590 °C were observed as shown in Fig. 6. The results show the formation of mixed phase of α -Fe and NbN precipitates. And it is expected that excess Nb and B of about 20 at. % form Nb–B rich intergranular amorphous layer, if all the nitrogen combine with Nb to form NbN precipitates, presumably. Thus, it was considered that the film consisted of three phases: a fine crystalline α -Fe phase whose grain size is 5–10 nm, a Nb–B rich amorphous phase and Nb–nitride precipitates with a size of less than 3 nm. On the other hand, it was reported that annealed Fe–Nb–B films⁴ have two phases: α -Fe grains with the size of about 10 nm and Nb–B amorphous phase. The finer α -Fe grains were obtained in Fe–Nb–B–N film as compared to Fe–Nb–B film. It results from suppressing the growth of α -Fe grains by the intergranular amorphous phase

FIG. 6. TEM microstructure (bright field, bcc-Fe dark field and NbN dark field) and SAD patterns of $\text{Fe}_{70}\text{Nb}_{14}\text{B}_{11}\text{N}_5$ film annealed at 590 °C. (A): α -Fe (110) diffraction pattern. (B): NbN diffraction pattern.

as well as Nb–nitride precipitates. From above results, it is concluded that nitrogen addition in Fe–Nb–B system was effective on α -Fe grain refinement. Herzer⁵ suggested that the effective permeability increases in proportion with the inverse of D^6 (D : grain diameter) through the decrease in effective magnetocrystalline anisotropy. Therefore, the high permeability for annealed $\text{Fe}_{70}\text{Nb}_{14}\text{B}_{11}\text{N}_5$ film as shown in Fig. 4 can be considered to be mainly due to the reduction of grain size of α -Fe.

IV. CONCLUSIONS

The effects of nitrogen addition in Fe–Nb–B system on magnetic properties and microstructure were investigated. Considerably enhanced soft magnetic properties were obtained by adding nitrogen. The saturation magnetization, coercivity and effective permeability at 10 MHz were 16.5 kG, 0.13 Oe and 5000, respectively. These good soft magnetic properties of the $\text{Fe}_{70}\text{Nb}_{14}\text{B}_{11}\text{N}_5$ film were mainly due to the decrease of the grain size of a α -Fe phase by the mixed effect of the intergranular amorphous phase as well as Nb–nitride precipitates. Therefore, nitrogen addition to a Fe–Nb–B system was considered to be an effective method for improving soft magnetic properties.

As-deposited Fe–Hf–C–N nanocrystalline thin films are investigated to improve soft magnetic properties by controlling both the compositions of the films and sputtering conditions, such as input power and N₂ partial pressure. As-deposited Fe–Hf–N thin films are also investigated for the applications to simplify the fabrication of magnetic devices. The as-deposited Fe–Hf–C–N and the as-deposited Fe–Hf–N thin films are fully nanocrystallized during deposition by controlling the composition and sputtering condition. The thin films show the excellent soft magnetic properties of saturation magnetization ~ 17.5 kG/ ~ 16.5 kG and coercivity ~ 0.5 Oe/ ~ 0.5 Oe when the compositions of each film are 6.8–7.2 at % Hf, 2.0–2.5 at % C, 9.8–10.8 at % N, and balanced Fe/6.3–7.0 at % Hf, 13.2–14.0 at % N, and balanced Fe, respectively. Both of the thin films exhibit an outstanding frequency dependence of permeabilities, i.e., the effective permeabilities of the films remain flat over 3000 up to 100 MHz. © 1998 American Institute of Physics.

I. INTRODUCTION

A demand for high performances in miniaturized electronic/electrical equipment forces soft magnetic materials to play an important role in micromagnetic devices including thin film inductors or transformers operating at high frequency (≥ 10 MHz). Thus soft magnetic thin films with excellent frequency dependence are strongly required as core materials. Soft magnetic thin films based on iron-rich Fe–Ta, Fe–Nb, Fe–Zr, and Fe–Hf have been investigated, and the enhancement of soft magnetic properties are obtained by adding B, C, and N.^{1–3} However, the excellent soft magnetic properties of Fe-based thin films are only obtained after post heat treatment which nanocrystallizes the deposited films at a temperature of 300–600 °C.

We reported that as-deposited Fe–Hf–C–N thin films have nanocrystalline structures and good soft magnetic properties, coercivity (H_c) of 0.5 Oe, saturation magnetization ($4\pi M_s$) of 13 kG, and effective permeability (μ_{eff}) over 3000 up to 100 MHz.⁴ The as-deposited films are applicable to magnetic devices which have not been heat treated, since heat treating deteriorates components and materials that are sensitive to the high temperature exposure. Thin films with higher $4\pi M_s$ are more favorable in practical applications. Thus, the magnetic properties of as-deposited Fe–Hf–C–N thin films are investigated to increase $4\pi M_s$ by controlling the deposition conditions and as-deposited ternary Fe–Hf–N thin films are also investigated for easy fabrication.

II. EXPERIMENTAL PROCEDURE

As-deposited Fe–Hf–C–N and Fe–Hf–N thin films have been prepared by a reactive magnetron sputtering method in a nitrogen atmosphere. The pellets of Hf and C are put on the pure Fe target to control thin film compositions. The flow of Ar gas is maintained at 20 sccm, and N₂ partial pressure is regulated in the range from 0% to 10% in order to obtain the films with various nitrogen contents. Both the mixed gases are introduced into the chamber after it has been evaluated to a pressure below 1×10^{-6} Torr. The working pressure is maintained at 1 mTorr. The distance between the target and the water-cooled Si(001) substrate is 6 cm. The rf input power varies from 150 to 550 W. The film thickness is 1 ± 0.2 μm , measured by a stylus profiler. The compositions and the microstructures of the films are analyzed by Auger electron spectroscopy (AES), Rutherford backscattering spectroscopy (RBS), x-ray diffraction with Cu K_α , and transmission electron microscopy (TEM). The magnetic properties of the films are measured by a vibrating sample magnetometer (VSM) and the magnetic easy/hard directions in plane are determined by a B - H loop tracer. The frequency dependence of μ_{eff} is obtained in the hard direction by using an eight-figure coil method. The electrical resistivity of the films is measured by a four-point probe method.

III. RESULTS AND DISCUSSION

The saturation magnetization of as-deposited Fe–Hf–C–N and Fe–Hf–N thin films varies with the rf input power as shown in Fig. 1(a). At 150 W, as-deposited films are not saturated by the external field up to 1 kOe. The $4\pi M_s$ of the as-deposited films are relatively small because of an Invar

^{a)}Electronic mail: hijkim@kistmail.kist.re.kr

FIG. 1. (a) Saturation magnetization ($4\pi M_s$) and (b) coercivity (H_c) as a function of rf input power. [An applied field (H_a) of 100 Oe but in case of input power of 150 W, the films are saturated by $H_a = 1$ kOe, $4\pi M_s$: (□) Fe-Hf-C-N, (■) Fe-Hf-N, H_c : (○) Fe-Hf-C-N, (●) Fe-Hf-N, the error range of data points is $\pm 5\%$.]

effect. Above 300 W, the $4\pi M_s$ of the films are coincident with Fe content. The maximum values of $4\pi M_s$ are 17.5 and 16.5 kG, respectively. The H_c of both the films decrease as the rf input power increases as shown in Fig. 1(b), and the minimum in H_c , $H_c = 0.5$ Oe, is obtained at 450 W. The μ_{eff} of the as-deposited films shows a good flat dependence on frequency, which remains around 3000 up to 100 MHz. As shown in Fig. 3(b), the μ_{eff} decreases slightly at the input power of 550 W. The best soft magnetic properties are observed at 450 W.

Figure 2 shows the effect of N_2 partial pressure on the soft magnetic properties of Fe-Hf-C-N and Fe-Hf-N thin films. All the films with different N contents are saturated at an applied field of 100 Oe. At low N_2 partial pressure (3%–4% and 4%–6%), $4\pi M_s$ are relatively small, which is presumed to be due to an Invar effect. Nitrogen, introduced during deposition, enhances the $4\pi M_s$ of the films. The maximum values for both the films are ~ 17.5 and ~ 16.5 kG at 6%–8% and 7%–8.5% of P_{N_2} , respectively. The coercivities of both the films have a minimum value at 5%–6.5% and 7%–8% of P_{N_2} . The minimum coercivities of both the films are about 0.5 Oe, as shown in Fig. 2(b). The addition of nitrogen strongly affects the μ_{eff} as shown in Fig. 3(a). The μ_{eff} of both the films increases with the introduction of nitrogen and reaches the maximum of 3000 in the range of 5.5%–6% and 7.5%–8% of P_{N_2} for Fe-Hf-C-N and Fe-Hf-N, respectively, and remain flat up to 100 MHz without any loss until several 10 MHz. However, excessive N con-

FIG. 2. (a) Saturation magnetization ($4\pi M_s$) and (b) coercivity (H_c) as a function of N_2 partial pressure. [An applied field (H_a) of 100 Oe, $4\pi M_s$: (□) Fe-Hf-C-N, (■) Fe-Hf-N, H_c : (○) Fe-Hf-C-N, (●) Fe-Hf-N, the error range of data points is $\pm 5\%$.]

FIG. 3. Effective permeability at 100 MHz (measured in the hard direction) with (a) N_2 partial pressure and (b) rf input power. The films show a flat frequency spectrum in optimum condition.

tent in the films decreases the μ_{eff} near $P_{N_2} = 10\%$. On the other hand, the μ_{eff} measured in the easy direction is not constant and very small (about several 10–100). As a result of AES and RBS analysis, the $\text{Fe}_{79.9-81.1}\text{Hf}_{6.8-7.2}\text{C}_{2.0-2.5}\text{N}_{9.8-10.8}$ and $\text{Fe}_{79.0-80.6}\text{Hf}_{6.0-7.0}\text{N}_{13.2-14.0}$ thin films have the best soft magnetic properties. Actually, the films with the content of 70–82 at % Fe in the case of Fe-Hf-C-N and Fe-Hf-N exhibit such excellent soft magnetic properties when the ratio of C+N/Hf and N/Hf is 1.8–1.9 and 2.0–2.2, respectively.⁴ The value of N/Hf is larger than that of C+N/Hf for optimum compositional condition, because the solubility of nitrogen in α -Fe is larger than that of carbon in α -Fe.

The variations of x-ray diffraction patterns with the addition of N and rf input power are shown in Figs. 4 and 5, respectively. Figures 4(a) and 5(a) show that the films deposited at the input power of 150 W are amorphous or mixed phase of amorphous and crystal, and that high input power generally crystallizes the films during deposition. Figures 4(b) and 5(b) show that nitrogen enhances the crystallization of the films from a mixed phase of crystal and amorphous,

FIG. 4. X-ray diffraction patterns [(●) α -Fe (110), (200), (211) and (○) Hf precipitates (111), (200) in order] of Fe-Hf-C-N thin films with rf input power [(a)=150 W, (b)=300 W, (c)=450 W, (d)=550 W] and N_2 partial pressure [(e)=0%, (f)=3%, (g)=6%, (h)=8%, (i)=10%].

FIG. 5. X-ray diffraction patterns [(●) α -Fe (110), (200), (211) and (○) Hf precipitates (111), (200) in order] of Fe-Hf-N thin films with rf input power [(a)=150 W, (b)=300 W, (c)=450 W, (d)=550 W] and N_2 partial pressure [(e)=0%, (f)=4%, (g)=7.5%, (h)=8%, (i)=10%].

which is confirmed by TEM analysis. They also show that the excessive addition of nitrogen breaks the crystallinity of the films. Thus, as-deposited Fe-Hf-C-N and Fe-Hf-N thin films are completely crystallized in the case where the rf input power and N_2 partial pressure are well controlled. Figure 6 shows the high resolution TEM image of Fe-Hf-C-N film deposited at 450 W and $P_{N_2}=6\%$. The Fe-Hf-C-N films consist of finely grained α -Fe with a diameter of ~ 5 nm and Hf(C,N) precipitates of smaller size. The morphology of exceptionally small grains surrounded by Hf precipitates contributes to the excellent soft magnetic properties. The soft magnetic properties of the films are little affected, after annealing at 823 K for 30 min. It is explained by the morphology that Hf precipitates prevent α -Fe grains from growing during annealing.

In order to understand the excellent high frequency permeability, the electrical resistivities of the films are measured. The resistivities are around $100 \mu\Omega$ cm which is similar to those of other Fe-nanocrystalline films.^{2,3} It means that the excellent dependence of effective permeability is not mainly due to the decrease of eddy current loss by the decrease of electrical resistivity. The excellent dependency appears when the permeability is measured in the hard direction, which means the existence of in-plane magnetic anisotropy at the as-deposited films. A B - H loop tracer shows that the frequency dependence of effective permeability is more excellent when the anisotropy is well aligned in the hard direction than widely dispersed. It means that the degree of magnetic anisotropy dispersion is related with permeability dependence. However, magnetocrystalline anisotropy is known to be averaged out by the refinement of α -Fe grains (random anisotropy model).⁵ The existence of in-plane anisotropy of the films could be due to the stray field from magnetron ring and interstitial insertion of C and N in α -Fe.⁶ Due to fast deposition, carbon and nitrogen remain in

FIG. 6. High resolution TEM image of Fe-Hf-C-N thin film deposited at $P_{N_2}=6\%$ and 450 W shows the nanocrystallized α -Fe grains (white area) and Hf precipitates (dark area). In the ring pattern, the notation of Fe represents 110, 200, 211 of α -Fe and the notation of Hf does 111, 200, 220 of Hf(C,N), respectively, from the center.

the octahedral sites of the α -Fe lattice, which contributes to uniaxial anisotropy.⁷ Even though the uniaxial anisotropy due to the solute atoms leads to an increase of the net anisotropy, the softness of the films is still maintained; i.e., the resultant coercivity is low (0.5 Oe), but it is larger than that (≤ 0.1 Oe) of other Fe-based thin films.^{2,3}

IV. SUMMARY

Fe-Hf-C-N and Fe-Hf-N thin films can be completely crystallized by controlling N_2 partial pressure and input power. As-deposited $Fe_{79.9-81.1}Hf_{6.8-7.2}C_{2.0-2.5}N_{9.8-10.8}$ and $Fe_{79.0-80.6}Hf_{6.3-7.0}N_{13.2-14.0}$ nanocrystalline thin films exhibit such excellent soft magnetic properties of $4\pi M_s$ (17 and 16.5 kG) and H_c (0.5 Oe). The films show especially excellent frequency dependence of high permeability of about 3000 up to 100 MHz without any loss until several 10 MHz. As-deposited Fe-Hf-C-N and Fe-Hf-N thin films are composed of finely dispersed α -Fe (~ 5 nm) and smaller Hf precipitates. Thus, the exceptionally small grains and precipitates enhance the soft magnetic properties and show thermal stability up to 823 K.

Microstructure and soft magnetic properties of FeSiAl(Ti/Ta)(O)N

M. Hiramoto,^{a)} N. Matsukawa, H. Sakakima, Y. Ichikawa, and K. Ijima

Central Research Lab, Matsushita Electric Industrial Co., Ltd., Seika-cho, Kyoto 619-0237, Japan

The microstructure and magnetic properties of FeSiAl(Ti/Ta)(O)N films prepared by rf magnetron reactive sputtering were studied. The microstructure was controlled by changing the N₂ gas flow rate ratio [$\eta = N_2/(Ar+N_2)$] in the sputtering gas. The soft magnetic properties were observed after thermal treatment at around η of 2% and η of 20%, where the saturation magnetostrictions and the intrinsic stresses took small values. The film with η of 20% had a granular structure as mostly observed on nanocrystalline materials. On the other hand, the film prepared with η of 2% had the structure which consisted of needle shaped grains or dendritic grains. The composition of the granular grains and needle shaped grains were mainly Fe and FeSi, respectively. The film with η of 2% exhibited B_s of 1.3 T, permeability of 3000–8000 at 1 MHz, respectively, and realized a high corrosion resistance. The soft magnetic properties of the films with needle shaped grains are explained by two-dimensional random anisotropy effect. © 1998 American Institute of Physics. [S0021-8979(98)48711-5]

I. INTRODUCTION

Nanocrystalline soft magnetic materials with high saturation magnetic flux density (B_s) and/or high electrical resistivity have been intensively investigated.^{1,2} Generally speaking, nanocrystalline materials have a granular structure obtained from the amorphous state by thermal treatment. The soft magnetic properties are affected by the mean grain size and intergranular magnetic properties. The softness is explained by a three-dimensional random anisotropy model^{3,4} and/or magnetic ripple theory.⁵ However, there were few reports about the dependence of magnetic properties on grain shape as well as grain size. We investigated the magnetic, structural, and corrosive properties of sputtered FeSiAl(Ti/Ta)(O)N films, whose grain structures were controlled by introducing N₂ gas during sputtering. The films are expected to be sensitive on the grain structures because of the small magnetocrystalline anisotropy (K_1) of the FeSiAl system (i.e., the films have a relatively long ferromagnetic correlation length, L_0 , compared with that of Fe). In this article, we report on the nanocrystalline materials, which have new types of the granular structure.

II. EXPERIMENT

FeSiAl(Ti/Ta)(O)N films of 3 μ m in thickness were prepared onto ceramic substrates by rf magnetron sputtering using alloy targets with a dimension of 3 in in diameter or 5 \times 15 in. The sputtering gas was a mixture of Ar+N₂ or Ar+N₂+O₂. The flow rate ratio of N₂, $\eta = N_2/(Ar+N_2)$, was varied from 0% to 23% and the flow rate ratio of O₂ was kept at 0% or 0.5%. Thermal treatment was performed in a vacuum at 520 °C. The B_s , initial permeability along the hard axis (μ_i), and the saturation magnetostriction (λ_s) were measured by using a vibrating sample magnetometer (VSM), a figure-8 coil apparatus, and an optical cantilever method, respectively. The microstructure was observed by

using a transmission electron microscopy (TEM) and x-ray diffraction, (XRD). The internal stress was evaluated by the change in the bending of the substrate. The film composition was determined by using an electron probe microanalysis (EPMA) and a Rutherford backscattering spectrometry (RBS). The corrosion resistance of the films was evaluated by the change in B_s of the films immersed in the 0.5 N NaCl solution for 50 h. All the measurements were carried out at room temperature.

III. RESULTS AND DISCUSSION

A. Magnetic properties and magnetostrictive anisotropy

The compositions of the FeSiAl(Ti/Ta) films sputtered with Ar gas were determined by EPMA as Fe₇₆Si₁₉Al₃Ti₂ and Fe₇₆Si₁₉Al₂Ta₃. Figure 1 shows the dependence of initial permeability (μ_i) on the flow rate ratio of N₂ (η). The μ_i has two peaks at around η of 2% and η of 20%. In order to clarify the origin of the two peaks of μ_i , several properties were precisely studied as follows. Figure 2(a) shows dependence of the internal stress (σ) of the films on η . The plotted

FIG. 1. Initial permeability (μ_i) of the FeSiAl(Ti/Ta) films with changing the nitrogen flow rate ratio (η).

^{a)}Electronic mail: hiramoto@crl.mei.co.jp

FIG. 2. Internal stress (σ), saturation magnetostriction (λ_s), magnetostrictive anisotropy energy due to the internal stress ($1/2\lambda_s \times \sigma$), and the lattice spacing of (110) plane ($d_{(110)}$) of the FeSiAl(Ti/Ta) films with changing the nitrogen flow rate ratio (η).

σ includes the thermal stress caused by thermal treatment. The negative sign denotes compressive stress. Figure 2(b) shows the dependence of the saturation magnetostriction (λ_s) on η . The relationship between λ_s and η is very similar to that of λ_s and the concentration of Si in α -Fe.⁶ Using the value of σ and λ_s , the magnetostrictive anisotropy energy due to the internal stress ($1/2\lambda_s \times \sigma$) was calculated. The result is illustrated in Fig. 2(c). Compared with Fig. 1, the magnetostrictive energy for the films prepared with η of 3%–18% may explain the deteriorations of μ_i . Figure 2(d) shows the

dependence of the lattice spacing of the (110) plane, $d_{(110)}$, on η . The value of $d_{(110)}$ with increasing η of these films approaches 2.0268 Å, which is the value of α -Fe, though it includes the affection of the lattice strain caused by σ . Considering that the stress affection and the $d_{(110)}$ of Fe₃Si is 2.005 Å, it is clear that the main grain compositions of the prepared films are changed from FeSi to Fe by changing the η 's from 0% to 20%. This result agrees with the consideration of the magnetostriction change as mentioned above. Further, in the range over 20%, the expansion of $d_{(110)}$ and the increasing of λ_s are observed. It may suggest that the Fe grains of the films with an η of over 20% contained the interstitial N atoms and the concentration of the N atoms is considered to be larger than that of Fe–N films which were widely known to show soft magnetic properties. Accordingly, the excess N atoms cause the deterioration of the soft magnetic property over an η of 20%.

B. Magnetic properties and microstructure

As mentioned above, the soft magnetic properties of FeSiAl(Ti/Ta)(O)N films are strongly affected by the magnetostrictive anisotropy energy. However, observing more precisely, it is noted that μ_i of the FeSiAlTiON film changes drastically from the μ_i of 1500 to 8000 with increasing the η from 0% to 3%, though the magnetostrictive energy is almost constant, μ_i of the prepared Fe₇₇Si₂₀Al₃ film was only 1800 at 1 MHz under the zero stress condition. Therefore, a μ_i of over 8000 of the FeSiAlTiON film cannot be explained only by the compositional change of FeSiAlTi grains by selective nitriding of Ti. Further, the reduction of K_1 caused by lattice strain⁷ is not expected because the change of $d_{(110)}$ in the η 's range of 0%–3% is small.

In order to investigate the influence of the microstructure on soft magnetic properties, TEM observations of the films were performed. Figures 3(a), 3(b), and 3(c) show the cross sectional dark field TEM images of FeSiAlTiON films prepared with an η of 20% and 2% using a 3 in target. The film prepared with an η of 20% [see Fig. 2(a)] consisted of the granular structure having a grain size smaller than 10 nm as observed in other nanocrystalline materials.^{1,2} It is clearly observed that the interparticle regions are in an amorphous state. On the other hand, the microstructure of the film prepared with an η of 2% [see Figs. 2(b) and 2(c)] consists of needle shaped fine grains grown perpendicularly to the film plane. The grain size is over 200 nm in length and 20 nm in width. Contrary to the film with an η of 20%, interparticle regions are not clearly observed. In other words, the film with an η of 2% is composed of mainly magnetic grains. A perpendicular anisotropy, which could be expected by the shape anisotropy of the needle shaped grains, was not observed in the hysteresis curve. The result is owing to the film structure mainly composed of magnetic grains as mentioned above. That is, the grains may have a strong exchange interaction with each other in the plane. The electron diffraction showed that the grains were randomly orientated crystallographically in the plane.

From the analysis of EPMA and RBS, the composition of the FeSiAlTiON film with an η of 2% was determined as

FIG. 3. The cross sectional dark field TEM micrographs of FeSiAlTiON films. (a) with an η of 20% and using a 3 in target. (b) and (c) with an η of 2% and using a 3 in target. (d) with an η of 2% and using a 5×15 in target.

($\text{Fe}_{76}\text{Si}_{19}\text{Al}_3\text{Ti}_2$) $_{94}\text{O}_1\text{N}_5$. Assuming that the grains are composed of a $\text{Fe}_{80}\text{Si}_{20}$ alloy, the ferromagnetic correlation length, L_0 is estimated³ as 35 nm. Taking a grain size of 20 nm in width, which is smaller than L_0 , and the random orientation of grains in the plane into consideration, the film satisfied the random anisotropy condition only in the plane. Therefore, we concluded that the good softness of the film with an η of 2% was caused by a two-dimensional random anisotropy effect in the plane as was observed in magnetic/nonmagnetic multilayered films.⁸

The shape of fine grains is interesting from the viewpoint of the film formation process. Generally speaking, a thick columnar structure is obtained by the condensation of several islandlike nucleuses with the surface diffusion. However, in the case of FeSiAlTiON with an η of 2%, only the needle shaped grain structure was observed instead of the thick columnar structure. This may indicate that the surface diffusion length is suppressed. Figure 3(d) shows a cross sectional TEM image of the FeSiAlTiON film prepared with an η of 2% using a wider target (5×15 in). The microstructure consisted of unique dendritic grains. The growth directions of "branches" of the dendrite are consistent with the directions of the oblique incident particles. The thin dendritic grain is good evidence of the suppressing of the surface diffusion in the plane. Compared with the needle shaped grain film, the dendritic grain film showed a stronger uniaxial magnetic anisotropy in the plane. The anisotropy may be due to the difference of the exchange correlation length in the

FIG. 4. B_s and the change of $B_s(50)/B_s(0)$ of the FeSiAlTiON films with changing the nitrogen flow rate ratio (η).

plane direction caused by the size and the shape of dendritic grains grown anisotropically owing to the oblique incident.

C. Corrosion resistance

Figures 4(a) and 4(b) show the dependence of B_s and the corrosion resistance, $B_s(50)/B_s(0)$ which is estimated with the change of B_s of the films on η . Whereas $B_s(50)$ denotes the B_s of the films after immersing the films in the 0.5 N NaCl solution for 50 h. The B_s shows a broad maximum at around an η of 5–15%. The increment of B_s is due to the segregation of the additive element out of α -Fe. The $B_s(50)/B_s(0)$ takes a minimum value at around an η of 15%. The high corrosion resistance in the low η 's range is realized by an additive which passivates the grain surface. On the other hand, in the high η 's range, the interparticle region in the amorphous state prevents the α -Fe grains from corrosion.

New applications of high resistivity magnetic films, such as Fe-Hf-O and Co-Fe-Hf-O as thin film inductors and flux gate magnetic sensors, were investigated. These soft magnetic films with nanocrystalline structure and high resistivity were deposited on glass substrate by using the oxygen reactive sputtering method. Planar sandwich thin film inductors developed by using Fe-Hf-O or Co-Fe-Hf-O films had a higher quality factor than that of an amorphous Co-Ta-Hf film inductor. The dc-dc converter using the Fe(Co-Fe)-Hf-O film inductor had higher conversion efficiency. These high resistivity magnetic films were also applied to a flux gate magnetic sensor operated at high frequencies over 1 MHz. Both high frequency excitation and high permeability (owing to the low eddy current loss) enabled us to increase the sensitivity, e.g., 39 mV/Oe/turn at 5 MHz when using a 3 μm thick Fe-Hf-O film (12 \times 6 mm² area). © 1998 American Institute of Physics. [S0021-8979(98)22311-5]

I. INTRODUCTION

In recent years, the micromagnetic devices, such as magnetic thin film inductors¹ (transformers²) and thin film flux gate sensors,³ have been developed to miniaturize the magnetic components in electronic equipment. Both high frequency excitation and thin film structure enable us to make the passive component smaller. However, in order to develop the high performance magnetic thin film devices, it is necessary to suppress the excess losses due to eddy currents. The authors developed the nanocrystalline Fe(Co-Fe)-Hf-O films with good soft magnetic properties and high electrical resistivity,⁴ and reported the planar inductor application.⁵

In this study, new applications of the Fe(Co-Fe)-Hf-O magnetic films were investigated. First, in order to make planar sandwich inductors smaller than the already reported inductors⁵ using a meander coil pattern and magnetic films, a square spiral pattern was used in the inner coil, which was sandwiched by top and bottom magnetic films. In the developed 10 \times 10 mm² size inductors, 0.53–0.80 μH inductances and the maximum quality factor of 16 at 10 MHz were obtained. Second, a flux gate magnetic field sensor was developed, which had the outer exciting coil, outer detecting coil, and the inner magnetic film. High resistivity magnetic films enabled us to increase the sensor sensitivity with increasing frequency, due to small eddy currents.

II. EXPERIMENTAL PROCEDURE

High resistivity nanocrystalline Fe(Co-Fe)-Hf-O films were produced on a glass substrate using oxygen rf sputter deposition method. Some properties of the 3 μm thick magnetic films are shown in Table I. For a comparison, the amorphous Co-Ta-Hf metal film is also shown in Table I. In order to induce uniaxial anisotropy, the Fe-Hf-O film was

annealed in the presence of a magnetic field of 2 kOe, and a temperature of 573 K for a time of 1 h, in vacuum. Uniaxial anisotropy was also induced in the Co-Fe-Hf-O film, by carrying out the deposition in the presence of the dc magnetic field applied to the substrate. From results of the transmission electron microscopy (TEM) and nano-beam energy dispersive x-ray (EDX) analyses, the high resistivity magnetic films had a nanocrystalline structure consisting of nanoscale Fe(Co-Fe) rich grains and Hf-O rich amorphous matrix. Consequently, these films exhibited high resistivity due to the Hf-O rich matrix.

First, high resistivity magnetic films were used to make small size planar inductors used for 5 MHz operation, dc-dc converters. Figure 1 shows a schematic illustration of the developed inductor, which had the multilayered structure composed of 10 \times 10 mm² square spiral coil sandwiched by the top and bottom magnetic layers. These materials were held together by synthetic resin, so planar sandwich structure is preserved.

Second, the flux gate magnetic sensor was developed by using high resistivity magnetic films. Figure 2 is the sensor structure. The exciting coil (Ne) and detecting coil (Nd) were wound together (Ne=10, Nd=10) to form the solenoid structure. The 3 μm thick rectangular magnetic film (12 \times 6 mm²) was inserted into the inner cavity of the solenoid to excite to the hard magnetization direction (short axis of rectangular film).

III. RESULTS AND DISCUSSION

The frequency dependence of permeability of these films was measured by using the parallel line method,⁶ and this is shown in Fig. 3. High resistivity magnetic films such as Fe(Co-Fe)-Hf-O had good frequency response (permeability) and low loss tangent ($\tan \delta$).

TABLE I. Some properties of Fe-Hf-O, Co-Fe-Hf-O, and Co-Ta-Hf films.

Magnetic film	Fe-Hf-O	Co-Fe-Hf-O	Co-Ta-Hf
Composition (at. %)	Fe ₆₁ Hf ₁₃ O ₂₆	Co ₄₄ Fe ₁₉ Hf ₁₅ O ₂₂	Co ₈₃ Ta ₆ Hf ₁₁
Saturation magnetization	13 kG	10.9 kG	8.1 kG
Anisotropy field	7.5 Oe	60.3 Oe	10.3 Oe
Resistivity	500 μΩ cm	1700 μΩ cm	170 μΩ cm

FIG. 1. Schematic illustration of planar sandwich inductor.

FIG. 2. Schematic illustration of flux gate sensor.

FIG. 3. Frequency dependence of permeability.

FIG. 4. Frequency characteristic of planar sandwich inductors.

Figure 4 shows the frequency characteristics of the planar sandwich inductors using Fe-Hf-O, Co-Fe-Hf-O, and Co-Ta-Hf film. The inductances at 1 MHz were 0.53–0.80 μH, and these were nearly constant up to 10 MHz, except for the Co-Ta-Hf film inductor. Though the cutoff frequency of μ' was about 90 MHz in 3 μm thick Co-Ta-Hf film, the inductance was gradually decreasing in the MHz band. This is mainly due to its low electrical resistivity. As shown in Fig. 5, the eddy currents in the top and bottom magnetic layers are not only due to the in-plane flux component, but also due to the perpendicular flux component. In particular, the latter component causes larger in-plane eddy current than that due to the former component. Therefore, it is important to increase the resistivity of the magnetic layer. In fact, the maximum quality factor of up to 16 was obtained through the inductor using the highest resistivity Co-Fe-Hf-O film.

Figure 6 shows the load current versus efficiency curves in the 5 MHz switching boost converter using planar sandwich inductor. The converter using Fe(Co-Fe)-Hf-O film inductors had higher efficiencies than those in case of Co-Ta-Hf film inductor. When the load current was large, the

FIG. 5. In-plane eddy current due to perpendicular flux.

FIG. 6. Efficiency vs load current curves measured in 5 MHz switching boost converter using planar sandwich inductor, with 3.6 V input and 4.6 V output condition.

efficiencies were nearly the same. This is owing to the large dc copper losses in the inductors.

The flux gate sensors were produced by using Fe-Hf-O and Co-Ta-Hf films, since both films had relatively high permeability. Figure 7 is the relationship between second harmonic amplitude V_{2p} across the differential detecting coil and the external dc field H_{ext} , where frequency f was 1 MHz, and exciting current amplitude I_{max} was 700 mA. The field sensitivities S ($=dV_{2p}/dH_{ext}$) were about 100 mV/Oe and 77 mV/Oe in the Fe-Hf-O and Co-Ta-Hf, respectively. The Fe-Hf-O film flux gate sensor had higher sensitivity than that of the Co-Ta-Hf film sensor. In order to get higher sensor sensitivity, it is important not only to have high permeability, but also to have high resistivity, in the magnetic films used in the sensors. Figure 8 shows the frequency dependence of the sensor sensitivity S . The sensitivities were nearly proportional to the $f^{0.9}$. However, the sensitivity of the Co-Ta-Hf film sensor didn't become higher over 4

FIG. 7. Relationship between external magnetic field H_{ext} and second harmonic amplitude V_{2p} in flux gate sensor.

FIG. 8. Frequency dependence of sensitivity in flux gate sensor.

MHz. The similar sensitivity saturation was also observed over 6 MHz in the Fe-Hf-O film. The saturation frequency relates to the high frequency loss, that is, the magnetic loss due to the eddy current and winding loss due to the skin and proximity effects. Since the high frequency loss, which is described as the equivalent parallel resistance in the equivalent parallel circuit, gives rise to the degradation of the core excitation, it is necessary not only to use high permeability and low loss magnetic material, but also to establish the optimum device structure to reduce the excess losses (to get high sensitivity).

IV. SUMMARY

To develop high performance micromagnetic devices, some applications of high resistivity nanocrystalline magnetic films Fe(Co-Fe)-Hf-O were investigated. The results obtained were as follows.

(1) Planar sandwich inductors using high resistivity magnetic films had higher quality factor exceeding 10 in the MHz band, and enabled us to increase efficiency in the high frequency energy conversion.

(2) Solenoid flux gate sensor using high resistivity and high permeability magnetic film had higher sensitivity.

Study on the in-plane uniaxial anisotropy of high permeability granular films

W. D. Li, O. Kitakami, and Y. Shimada

Research Institute for Scientific Measurements, Tohoku University, 2-1-1 Katahira, Aoba, Sendai 980-77, Japan

We have investigated the uniaxial magnetic anisotropy of the high resistivity Fe–Al–O granular films prepared by sputtering. It is found that application of external dc field during film deposition and post-annealing treatments give rise to no serious effects on the magnetic anisotropy. In contrast, the incident angle of sputtered particles to the substrate greatly affects the strength and the direction of the anisotropy. These results suggest that the magnetic anisotropy is induced by a shape anisotropy due to anisotropic morphology in the films. The temperature dependence of the anisotropy constant, however, does not obey the usual shape anisotropy relationship $K_u(T) \propto M_s(T)^2$. In the present article, we propose an anisotropic coupling model in order to explain the uniaxial anisotropy found in these granular films, where the magnetic coupling between Fe grains is assumed to be anisotropic in the film plane due to the presence of low T_c intergranular phase which bridges the gap between Fe grains in one direction but not in the orthogonal direction. This model satisfactorily explains the temperature dependence of $K_u(T)$ and $M_s(T)$ for all Fe–Al–O granular films prepared in the present experiment. This agreement between the experiments and the theory implies that the magnetic anisotropy of the granular films is remarkably influenced by the magnetism and spatial distribution of the low T_c intergranular phase. © 1998 American Institute of Physics. [S0021-8979(98)35211-1]

I. INTRODUCTION

High resistivity granular films receive much attention from the standpoint of low core-loss films for high frequency use.^{1–4} Since the high frequency behavior of the permeability is mainly dominated by the magnetic anisotropy of the films, it is essential to accurately control the anisotropy. However, the anisotropic field present in the granular films is so high (from $H_k=20$ Oe to about 300 Oe) that the conventional theories of induced anisotropy are inapplicable. Moreover, appearing in very fine Fe or Co crystals with no preferential crystal orientation, it cannot be explained by contribution from the crystalline anisotropy either. It has been reported that the anisotropy can be induced by magnetic field annealing in Co-based granular films,⁵ but not in Fe-based ones.

The origin of high uniaxial anisotropy appeared in the granular films still remains unclear to date.

In this article we mainly present the experimental procedure, the anisotropic exchange coupling model, the calculation of the microscopic shape anisotropy, and a possible method of controlling the anisotropy in order to improve the high frequency characteristics of the high resistivity granular films.

II. EXPERIMENT

Fe–Al–O granular films were prepared on glass substrates in a rf magnetron sputtering system at ambient temperature, with the base pressure less than 2×10^{-6} Torr and argon gas pressure of 4 mTorr. For some samples, a static field of 200 Oe was applied parallel to the substrate surface during the film deposition in order to check the effect of the field on the magnetic anisotropy. The film composition was

varied by changing the number of Al_2O_3 chips on an Fe target and were determined by wavelength dispersive x-ray analysis. The film thickness was kept constant at 2 μm . Three kinds of substrate holders were utilized to change the incident angle of sputtered particles to the film normal (0° , 20° , 30°).⁶ Thus obtained Fe–Al–O films were annealed in vacuum at 200–450 $^\circ\text{C}$ for 4 h under the dc field (1000 Oe) applied along either the easy or hard axis of the samples in the film plane. The crystalline structures and the magnetic properties were evaluated by an x-ray diffractometer (XRD) and a vibrating sample magnetometer (VSM), respectively.

III. RESULTS AND DISCUSSION

We found that both the direction and the strength of uniaxial anisotropy strongly depended on the substrate positions, namely, the easy axis lies along radial direction from the center of the substrate holder⁴ and its magnitude drastically increases with the average incident angle $\langle \theta \rangle$ of sputtered particles (see the inset in Fig. 2). On the other hand, the external field during film deposition gave rise to little changes in the distribution and the strength of the uniaxial magnetic anisotropy, indicating that the anisotropy is not induced by the magnetic annealing effect. In order to make this clear, the change of anisotropy constant (K_u) was measured after annealing in 1000 Oe dc magnetic field parallel or perpendicular to the easy direction of the samples. Figure 1 shows the dependence of K_u on annealing temperature and magnetic field direction. From this figure, it is clear that the anisotropy does not depend on the magnetic field direction. Therefore, it can be concluded that the anisotropy of Fe–Al–O film is not field induced. Figure 2 shows the anisotropy field (H_k) of the as-deposited Fe–Al–O films as a func-

FIG. 1. Anisotropy dependence on annealing temperature and magnetic field direction for Fe-Al-O granular films.

tion of average incident angle $\langle\theta\rangle$. The magnitude of the uniaxial anisotropy is exclusively governed by $\langle\theta\rangle$ irrespective of other deposition conditions such as different substrate shapes and dc magnetic field. These results lead us to think that oblique incidence of sputtered particles causes the uniaxial anisotropy of the Fe-Al-O films. If an anisotropic film morphology develops by the oblique incidence effect,⁷ one may expect a magnetic anisotropy due to shape anisotropy. Then, the magnetic anisotropy would be proportional to the square of M_s . We measured $M_s(T)$ and $K_u(T)$ as a function of temperature in the range of 77–673 K, as shown in Fig. 3 with \circ and \triangle , respectively. We note that $K_u(T)$ drops off more rapidly than $M_s(T)^2$ (\square). Therefore, it is unlikely that a simple anisotropic morphology plays a dominant role for the occurrence of uniaxial magnetic anisotropy in the granular films. Moreover, as seen in Fig. 3, the M_s - T curve is quite different from that of pure α -Fe⁸ (—), indicating that the granular film contains a certain amount of low T_c phase in addition to α -Fe. Since we only observed the diffractions due to α -Fe in the XRD scans of the granular films, the unknown low T_c phase seems to be amorphous or severely disordered. Thus, it is reasonable to assume that the granular film consists of α -Fe grains and a low T_c disordered phase.⁹

Based on the above experimental results, we propose an anisotropic coupling model schematically shown in Fig. 4(a). In this model, the magnetic coupling between Fe grains is assumed to be anisotropic in the film plane due to the pres-

FIG. 2. Incident angle dependence of anisotropy field H_k for Fe-Al-O granular films.

FIG. 3. Temperature dependence of M_s and H_k for an Fe-Al-O granular film.

ence of the low T_c intergranular phase, which anisotropically bridges the gap between Fe grains. This situation can be realized if the Fe content in the boundaries along the x direction is larger than along y direction. A simplified model for calculation is shown in Fig. 4(b). This model assumes rectangular shaped Fe grains and boundaries. The main difference of this model from that in Fig. 4(a) is that the exchange coupling appears only in the boundaries distributed along the x direction. In the actual films, the boundaries along the y direction may also be ferromagnetic, but this model assumes the exchange coupling along the x direction is strong enough to neglect them. According to the microscopic shape anisotropy model proposed by Fujiwara,¹⁰ the magnetostatic energies when the film is fully magnetized in the x and y directions are, respectively, given by

$$\epsilon_x = 2\pi M_s^\alpha (M_s^\alpha - M_s') \delta / a, \quad (1)$$

$$\epsilon_y = 2\pi (M_s^\alpha)^2 \delta / a, \quad (2)$$

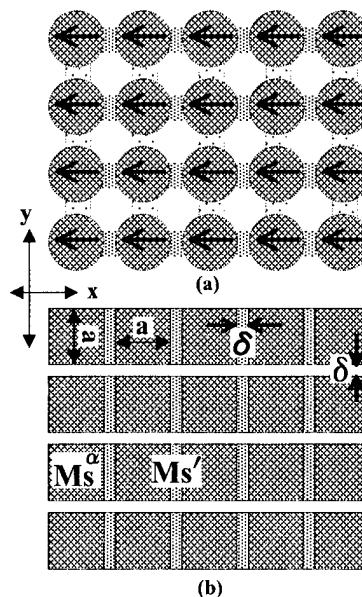

FIG. 4. Anisotropy model for Fe-Al-O granular films.

for $\delta \ll a$, where δ and a are the size of intergranular space and Fe granule, M_s^α and M_s' are the saturation magnetizations for the α -Fe phase and the low T_c boundary phase. The anisotropy energy is then given by the magnetostatic energy difference between Eqs. (1) and (2):

$$K_u = \Delta \epsilon = \epsilon_y - \epsilon_x = 2 \pi M_s^\alpha M_s' \delta / a. \quad (3)$$

Thus, the shape anisotropy is determined by the microscopic structural parameters δ/a and M_s' . From Eq. (3), the temperature dependence of the normalized anisotropy energy can be rewritten as

$$\frac{K_u(T)}{K_{u0}} = \frac{M_s^\alpha(T)}{M_{s0}^\alpha} \times \frac{M_s'(T)}{M_{s0}'}, \quad (4)$$

where K_{u0} , M_{s0}^α , and M_{s0}' are the values at liquid nitrogen temperature. When the volumetric ratios for α -Fe grains and low T_c phase are, respectively, V^α and V' , $M_s(T)$ of the film can be expressed as

$$M_s(T) = M_s^\alpha(T) V^\alpha + M_s'(T) V'. \quad (5)$$

At the Curie temperature of the low T_c intergranular phase ($T = T_c'$), Eq. (5) becomes

$$M_s(T_c') = M_s^\alpha(T_c') V^\alpha. \quad (6)$$

According to Eq. (3), the in-plane uniaxial anisotropy K_u vanishes at $T = T_c'$. Therefore, T_c' is defined as the temperature at which K_u becomes zero. Using Eqs. (5) and (6), Eq. (4) can be rewritten as

$$\frac{K_u(T)}{K_{u0}} = \frac{M_s^\alpha(T)}{M_{s0}^\alpha} \times \frac{M_s(T) - M_s(T_c') M_s^\alpha(T) / M_s^\alpha(T_c')}{M_{s0} - M_s(T_c') M_{s0}^\alpha / M_s^\alpha(T_c')}. \quad (7)$$

Substituting the magnetization values at various temperatures into Eq. (7), one can predict the temperature dependence of $K_u(T)$. Thus the predicted $K_u(T)$ perfectly coincides with the experimental results for all Fe-Al-O granular films prepared in the present study as shown in Fig. 5. We also found that the temperature dependence of $M_s(T)$ was well fitted by Eq. (5). Thus, the present anisotropic coupling model is appropriate to explain the uniaxial anisotropy of the Fe-Al-O granular films.

This model is also supported by measurement of the frequency dependence of permeability for Fe-Al-O films with various anisotropy fields H_k .^{3,4} By fitting the frequency dependence of permeability for Fe-Al-O films using the Landau-Lifshitz equation for magnetic films with uniaxial anisotropy, it is found that the damping constant becomes bigger for weak H_k . This implies the exchange coupling between the Fe grains becomes weaker, giving rise to a spin fluctuation to which the Landau-Lifshitz model is inapplicable.

As mentioned above, it is clarified that the magnetism of the boundary phase plays an important role for the magnetic anisotropy of the granular films. Therefore, one can optimize the magnetic anisotropy of the granular films for high frequency use by controlling the magnetism of the boundaries. For Fe-Al-O granular films, adjusting the slope of substrate surface is effective to control it.

FIG. 5. Comparison of measured and calculated K_u for Fe-Al-O granular films.

IV. SUMMARY

We have investigated the uniaxial magnetic anisotropy of Fe-Al-O granular films. The main results can be summarized as follows:

- (1) The high uniaxial anisotropy found in Fe-Al-O granular films is not field induced, because the application of a static field during film deposition and post-annealing give rise to no significant changes in the anisotropy.
- (2) The behavior of the magnetic anisotropy can be satisfactorily explained by the proposed anisotropic coupling model in which the magnetic coupling between Fe grains is anisotropic in the film plane due to the presence of the low T_c intergranular phase. The good agreement between the experiment and the theory indicates that the magnetic anisotropy is dominated by the magnetism and spatial distribution of the low T_c intergranular phase.

Soft magnetic properties of Co–Cr–O granular films

Takeshi Morikawa,^{a)} Motofumi Suzuki, and Yasunori Taga

Toyota Central R & D Laboratories, Inc., 41-1, Yokomichi, Nagakute, Aichi 480-11, Japan

Excellent soft magnetic properties have been achieved for Co–Cr–O granular films with nanoscaled grains of Co distributed in the amorphous intergranular regions of Cr_2O_3 . A rapid decrease in coercivity has been observed with the volume fraction of Co, and the minimum value of 0.39 Oe was obtained at 75.5 vol % of Co without postannealing. This value is one order of magnitude smaller than those of Co–Al–O and Co–Si–O sputtered films. The saturation magnetization, in-plane anisotropy field, and permeability below 800 MHz are 11.8 kG, 80 Oe, and 141, respectively. Because of its large saturation magnetization and in-plane anisotropy, the resonance frequency is estimated at 2.9 GHz. Therefore, Co–Cr–O granular films can be used in the high frequency devices operating over 2 GHz. © 1998 American Institute of Physics. [S0021-8979(98)29411-4]

I. INTRODUCTION

In recent years, soft ferromagnetic properties of granular thin films have attracted much attention for applications to magnetic devices operated in the GHz region such as micro-inductors, noise filters, and microsenors. High ferromagnetic resonance (FMR) frequency, large electrical resistivity ρ , and low coercivity H_c are required to reduce magnetic losses by FMR, eddy currents, and hysteresis. Up to now, soft magnetic properties of Fe–M–N,^{1,2} Fe–M–O,³ and Co–M–O⁴ films have been reported, where M are nonmagnetic materials such as B, Hf, Al, Si, Zr, etc. Among them, the Co–Al–O film⁴ shows a large FMR frequency of over 2 GHz and a high electrical resistivity of over 300 $\mu\Omega$ cm. Thus, they can be used in the GHz region. The mechanism of the soft magnetic properties of the Co–Al–O films is quantitatively understood by the random anisotropy model proposed by Herzer.⁵ The randomized magnetocrystalline anisotropy of each Co grain is effectively canceled within the ferromagnetic exchange length in the entire film. Therefore, the interaction between Co grains through the intergranular regions plays an important role in the soft magnetic properties.

On the other hand, the magnetic properties of Co-based granular films can be modified or enhanced, if the intergranular materials include 3d transition metals. However, such systems have not been investigated to date. In the present work, therefore, we have selected chromium oxide as the intergranular phase and achieved both a low coercivity and a high resonance frequency in the Co–Cr–O granular films.

II. EXPERIMENT

The Co–Cr–O thin films were deposited on glass and silicon (100) substrates in a magnetron sputtering system with a base pressure of $(4-8) \times 10^{-7}$ Torr. Co and Cr_2O_3 targets were sputtered in an Ar atmosphere of 3.0×10^{-3} Torr. In order to change the composition of the

samples, the deposition rate of Cr_2O_3 was varied over a wide range from 0 to 10 nm/min, while that of Co was kept constant at 16 nm/min. The thicknesses of films were 550 nm for all the samples. In order to induce unidirectional magnetic anisotropy, the films were deposited in the presence of a static in-plane magnetic field of 100–150 Oe. The substrate temperatures were below 50° during the deposition.

The structural and compositional characterization and the measurements of the electromagnetic properties were performed for the samples without any postannealing. Direct current resistivity was measured by the four-probe method. The structure was analyzed by x-ray diffractometry (XRD) with Cu $K\alpha$ radiation. The composition and chemical bonding were analyzed by x-ray photoemission spectroscopy (XPS) using a Mg $K\alpha$ x-ray source. Saturation magnetization $4\pi M_s$, coercivity H_c , and in-plane magnetic anisotropy field H_k were measured by a vibrating sample magnetometer (VSM). The complex permeability ($\mu = \mu' - j\mu''$) below 100 MHz was measured by the commercial permeance meter (Ryowa Electronics Inc.)⁶ together with a HP4194A impedance analyzer and that from 100 to 800 MHz was measured by the parallel line method^{7,8} using a HP8510C network analyzer. For the latter measurement, the measurement fixture was carefully designed to set its resonance frequency above 3 GHz.

FIG. 2. Dependence of dc electrical resistivity on Co fraction.

III. RESULTS AND DISCUSSIONS

A. Film structure

In the XPS spectra for our samples, only the peaks due to the metallic Co and Cr–O bond were observed, while peaks due to Co–O, Co–Cr bonds and metallic Cr were not detected. It is also confirmed by XPS that the target composition of Cr_2O_3 is preserved in the films. In the present article, we use a nominal volume fraction of Co to denote the composition of the samples.

Figure 1 shows a typical x-ray diffraction pattern for the Co–Cr–O film of 75.5 vol % of Co. The film shows broad diffraction peaks corresponding to hcp (10•0), (00•2), (10•1), and fcc (111) of Co. The average diameter of Co grains is estimated to be 4 nm by Scherrer's formula. These diffraction peaks are observed in the films of 70.7–100.0 vol % of Co. On the other hand, no diffraction peaks due to the crystalline of Cr_2O_3 are observed. A (110) peak of Cr at $2\theta = 44.39^\circ$ is negligible because no metallic Cr was observed by XPS. Consequently, in our samples, nanoscaled metallic Co grains less than 4 nm in diameter are distributed in the amorphous intergranular region of Cr_2O_3 .

B. Electric and magnetic properties

Figure 2 shows a dependence of dc resistivity ρ on the volume fraction of Co. The resistivity increases exponentially with decreasing volume fraction of Co. The values of ρ are 300–400 $\mu\Omega \text{ cm}$ around 75 vol % of Co, where the films exhibit soft ferromagnetism as discussed below. These values of ρ are comparable with those of the Co–Al–O films.

Figure 3(a) shows a dependence of coercivity on the Co volume fraction. It is remarkable that the coercivity strongly depends on the volume fraction of Co. The minimum coercivity is smaller by three orders of magnitude than that of pure Co film. As shown in Table I, the films including Co of 73.8–75.5 vol % have coercivities less than 2 Oe which are

FIG. 3. Dependence of (a) coercivity and (b) fractional magnetization of Co on the volume fraction of Co.

superior to those of Co–Al–O.⁴ Particularly, the sample of 75.5 vol % of Co exhibits a small coercivity and a large unidirectional anisotropy field of 80 Oe as shown in Fig. 4. The minimum coercivity in the easy axis is 0.39 Oe. This value is one order of magnitude smaller than the value of Co–Al–O.⁴ The coercivity in the hard axis is 1.8 Oe. The reason for the larger hard axis coercivity is likely to be due to the magnetic anisotropy dispersion. However, the coercivity in the hard axis is also smaller than that of Co–Al–O.

Figure 3(b) shows a dependence of the fractional saturation magnetization on the volume fraction of Co. Here, the fractional saturation magnetization is defined as the ratio of the total saturation magnetizations of the samples to the volume fraction of Co. The fractional saturation magnetizations show a plateau of 15.7 kG within the region of 100–75.5 vol % of Co. This suggests that the Co grains in the Co–Cr–O films maintain the same magnetization as that of pure Co film. Below 75.5 vol % of Co, the fractional magnetizations begin to decrease with decreasing the volume fraction of Co, while the coercivity begins to increase. Hence, excellent soft magnetic properties are dominated by the nanoscaled Co grains with the same magnetizations as pure Co and the minimum coercivity appears near the boundary where magnetizations of Co grains begin to decrease.

FIG. 4. In-plane M - H curves for 75.5 vol % of Co ($\text{Co}_{77}\text{Cr}_9\text{O}_{14}$).

TABLE I. Properties of Co–Cr–O films.

Composition		H_c (Oe)		$4\pi M_s$ (kG)	ρ ($\mu\Omega \text{ cm}$)
(vol % of Co)	(at. %)	Easy axis	Hard axis		
77.2	$\text{Co}_{80}\text{Cr}_8\text{O}_{12}$	17.0	24.6	11.9	310
75.5	$\text{Co}_{77}\text{Cr}_9\text{O}_{14}$	0.39	1.8	11.8	326
73.8	$\text{Co}_{74}\text{Cr}_{11}\text{O}_{16}$	1.7	10.2	11.4	396

FIG. 5. Dependence of hard-axis complex permeability $\mu = \mu' - j\mu''$ on frequency for film of 75.5 vol % Co. Solid and dotted lines are calculated μ' and μ'' , respectively.

The drastic change in coercivity above 75.5 vol % of Co is due to the decrease in grain size⁵ from 26 to 4 nm. On the other hand, below 75.5 vol %, it is considered that the change is caused by the gradual decrease in ferromagnetic coupling between Co grains as expected in Fig. 3(b). Compared with previously reported Co-based films,⁴ the present Co-Cr-O film shows small coercivity. It is considered that the ferromagnetic exchange length may be effectively modified by the intergrains. However, a detailed investigation is necessary to clarify the mechanism of the small coercivities of Co-Cr-O films.

Figure 5 shows the dependence of hard-axis complex permeability $\mu = \mu' - j\mu''$ on frequency for the film of 75.5 vol % of Co. Open and solid circles represent the real and imaginary part of the measured permeability, respectively. The real part of measured permeability keeps constant at $\mu' = 141$ below 800 MHz. On the other hand, the imaginary part is $\mu'' = 1$ below 300 MHz and then increases with frequency. The solid and dotted lines represent μ' and μ'' , respectively, calculated by using the solution of Landau-Lifshitz equations taking account of the coherent spin rotation as follows:^{9,10}

$$\mu = \frac{4\pi M_s \omega_0^2 ((\omega_0^2 - \omega^2) - j4\pi\lambda\omega)}{H_k((\omega_0^2 - \omega^2)^2 + (4\pi\lambda\omega)^2)}, \quad (1)$$

$$\omega_0^2 = 4\pi|\gamma|^2 M_s H_k, \quad (2)$$

where, ω_0 is the FMR frequency, γ is the gyromagnetic constant (here, 2.34×10^5 m/As), and λ is the relaxation frequency.

The calculated permeability agrees well with the measured ones. This indicates that the domain wall motion is

eliminated because of the operation at very high frequency. Furthermore, since the Co-Cr-O film has a large $4\pi M_s$ and H_k , the FMR frequency is estimated at about 2.9 GHz [Eq. (2)]. The skin depth of the film is estimated at 1.4 μm at 2.9 GHz and eddy current loss is negligible in this frequency region because of large ρ . In consequence, it is expected that the real permeability μ' keeps constant up to 2 GHz so that the present Co-Cr-O system is applicable to the high frequency devices operated over 2 GHz.

IV. CONCLUSION

Soft magnetic properties of Co-Cr-O granular films prepared by codeposition of Co and Cr_2O_3 are investigated. In the resulting films, nanocrystalline Co grains distributed in the amorphous intergranular regions of Cr_2O_3 . A drastic change in coercivity is observed depending on the volume fraction of Co. The excellent soft magnetic property has been achieved at 75.5 vol % of Co. The $4\pi M_s$ of 11.8 kG, H_k of 80 Oe, and H_c of 0.39 Oe are obtained. The value of H_c is one order of magnitude smaller than the previously reported Co-based films. The dc resistivity is 326 $\mu\Omega\text{cm}$. The real part of the permeability keeps constant at 141 up to 800 MHz and the FMR frequency is estimated at 2.9 GHz. Therefore, Co-Cr-O granular films can be used in the high frequency devices operated over 2 GHz.

Magnetic properties of Fe films deposited by Ar, Kr, and Xe ion beam sputtering

S. Iwatsubo, T. Takahashi,^{a)} and M. Naoe^{b)}

Toyama Industrial Technology Center, Takaoka, Toyama 933, Japan

Fe films have been deposited by ion beam sputtering using Ar, Kr, and Xe gases. The sputtering voltage V_S was varied in the range of 900–1800 V. The magnetic properties of the films had the significant relationship with the element of the sputtering gas. The saturation magnetization $4\pi M_S$ was 21 kG for Ar and 20 kG for Kr or Xe. The coercivity H_C took the minimum value of 5 Oe at V_S of 1200 V for Ar. The energy/the number of the energetic particles, such as the sputtered atoms and the recoiled ions bombarding to the substrate was calculated by Monte-Carlo simulation in the sputtering system with an amorphous Fe target. The average energy of the sputtered atoms E_S was 40–60 eV for Ar, 30–34 eV for Kr and 24–34 eV for Xe. The average energy of the recoiled ions E_R was 200–370 eV for Ar, 60–100 eV for Kr, and 25–50 eV for Xe. The energy was remarkably different among their sputtering gases with different atomic mass. The bombardment by the recoiled ions at the high energy reduced the coercivity H_C of the Fe films. © 1998 American Institute of Physics. [S0021-8979(98)35311-6]

I. INTRODUCTION

Pure Fe is one of the most representative materials with soft magnetism such as a low coercivity and a large saturation magnetization of 21.5 kG. So far, when Fe films were deposited by sputtering, their structure and properties significantly depended on the preparation condition.^{1–3} For the film preparation with good reproducibility it should be required to control the energy of the arrival particles to the substrate. The energy may be the most significant factor to characterize the properties of the deposited films.

In sputtering, both the energy and the flux of the sputtered atoms and the recoiled ions depends on the difference in atomic mass between the component elements of target and the sputtering gas. So, the sputtering using the gas with different atomic mass is an effective method to control the parameters. Therefore, the magnetic properties of Fe films may be controlled by sputtering with Kr and Xe instead of Ar.

In this study, the difference of magnetic properties of the Fe films among Ar, Kr, and Xe gases has been investigated using an ion-beam sputtering apparatus with the features of plasma-free deposition and good controllability. The Monte-Carlo simulation TRIM⁴ was used to estimate the energy and flux of the arriving particles, that is, the sputtered atoms and the recoiled ions, to the substrate plane.

II. EXPERIMENTAL PROCEDURE

The Fe films were deposited on water-cooled glass substrates using an ion beam sputtering apparatus with an ion source. It was Kaufman-type and the grid had a diameter of 2.5 cm. The target was a Fe disk of 99.9% in purity and 120 mm in diameter. The distance between the target and the

substrate was 200 mm. Pure Ar, Kr, and Xe with the different atomic mass were used as the sputtering gas. After the chamber was evacuated to the residual gas pressure lower than 6×10^{-5} Pa, the sputtering gas at flow rate of 2 sccm was introduced into the sputtering ion source. Gas pressure was 5.0, 11, and 30 mPa for Ar, Kr, and Xe, respectively. The current of the sputtering ion beam was fixed at 50 mA. Film thickness was approximately 300–350 nm. The internal stress σ was calculated from the measured value of the curvature of cantilever samples. The electrical resistivity ρ was measured by the four-terminal method. The saturation magnetization $4\pi M_S$ and the coercivity H_C of the Fe films were measured using a vibrating sample magnetometer (VSM).

III. RESULTS AND DISCUSSION

A. Simulation results and deposition rate

Figure 1 shows the schematic layout of the ion beam sputtering (IBS) apparatus used in this study and the angular distribution in energy of the Ar ions recoiled from the Fe target at the sputtering voltage V_S of 1200 V, as calculated by Monte-Carlo simulation TRIM. The TRIM calculations

^{b)}Faculty of Engineering, Tokyo Institute of Technology, Meguroku, Tokyo 152, Japan.

FIG. 2. V_S dependence of average energy of sputtered atoms E_S and ratio in arrival number R_A for Ar, Kr, and Xe as sputtering gas.

are based on a direct Monte-Carlo method applied to the transport of ions and recoils in an amorphous Fe target. The incident angle of the sputtering ion beam to target plane was equal to 45° . The substrate was parallel to the target plane. The calculation at 10 000 events was executed. The small dots in the figure correspond to the energy and the angular direction of recoiled ions. In this figure, the substrate was bombarded by the recoiled Ar ions at the high energy up to 800 eV. The flux of a large number of the recoiled ions was reflected from the ion source in the direction of the target plane to the substrate.

Figure 2 shows the V_S dependence of the average energy E_S of the sputtered atoms and the ratio in arrival number R_A of the recoiled ions to the sputtered Fe atoms to the substrate. Namely, R_A was given by

$$R_A = \frac{\text{Number of recoiled ions}}{\text{Number of sputtered Fe atoms}}.$$

The energy of the sputtered atoms and the recoiled ions was estimated from taking statistics of the particles arrived at the substrate surface as shown in Fig. 1. For Ar, E_S monotonically increased from 40 to 60 eV with an increase of V_S . For Kr and Xe, E_S gradually increased from 24 to 35 eV. On the other hand, R_A decreased with an increase of V_S . R_A was in the range of 0.07–0.16 for Ar, 0.03–0.07 for Kr, and 0.02–0.06 for Xe. The values of E_S and R_A for Kr and Xe were remarkably different from those for Ar.

Figure 3 shows the V_S dependence of the average energy E_R of the recoiled ions. E_R increased in proportion to an increase of V_S . The value of E_R was in the range of 200–380 eV for Ar, 60–100 eV for Kr, 20–50 eV for Xe. The magnitude in variation of E_R was larger than that of E_S . For Xe, E_R was at the almost same value. On the other hand, E_R for Ar was very high. Especially for Ar, the film surface was bombarded by the recoiled ions with E_R of 380 eV and R_A of 0.07 at V_S of 1800 V. It seems that the bombarding effect by the recoiled Ar ions is very serious for the growing Fe films.

Figure 4 shows the V_S dependence of the deposition rate R_D . R_D linearly increased with increase of V_S for Kr and Xe. On the other hand, R_D for Ar was almost constant value

FIG. 3. V_A dependence of average energy of recoiled ions E_R .

of 2.2 nm/min. This difference may be due to the re-sputtering effect by the recoiled ions to the substrate. Because the recoiled ions for Ar possess a high energy enough to sputter the surface region of film. The extent of R_D reduction by resputtering effect corresponded to the value estimated from R_A and the sputtering yield of Fe at each E_R .

B. Properties

Figure 5 shows the V_S dependence of the internal stress σ . The negative value of σ indicates compressive stress. σ monotonically decreased from -0.02 to -0.1 GPa with increase of V_S for Kr and Xe. On the other hand, for Ar, σ took the minimum value of -0.14 GPa at V_S of 1200 V. The absolute value of σ for Ar was larger than that for Kr and Xe. It was caused from the atom peening effect due to bombardment by the recoiled ions with the high energy. As a result, the films deposited under the Ar bombardment, that is, a bias sputtering,⁵ exhibited high internal stress.

Figure 6 shows the V_S dependence of the electrical resistivity ρ of the films. The film exhibited higher ρ than bulk pure Fe (about $10 \mu\Omega \text{ cm}$). ρ was almost constant for Kr and Xe. On the other hand, for Ar, ρ increased from 24 to 56

FIG. 4. V_A dependence of deposition rate D_R .

FIG. 5. V_A dependence of internal stress σ .

$\mu\Omega$ cm in proportion to V_s . Generally, the value of ρ strongly depended on the film structure. The variation of ρ may be attributed to electron scattering at the grain boundary of the microstructure in the films. The grain size of films for Ar seems to be smaller than that for Kr and Xe.

Figure 7 shows the V_s dependence of the saturation magnetization $4\pi M_s$ and the coercivity H_C . $4\pi M_s$ was nearly equal to that of bulk pure Fe for all gases. On the other hand, H_C decreased with increase of V_s for Kr and Xe. H_C was in the range from 10 to 20 Oe for Kr and from 10 to 30 Oe for Xe. For Ar, H_C took the minimum value of 5 Oe at V_s of 1200 V. H_C was remarkably different among sput-

FIG. 6. V_A dependence of electrical resistivity ρ .FIG. 7. V_A dependence of saturation magnetization $4\pi M_s$ and coercivity H_C .

tering gases, where for Ar was lowest. This result agreed exactly with the fact that the Fe films deposited with the ion bombardment such as bias sputtering¹ and double ion beam sputtering^{2,3} had lower H_C . Therefore, the decrease of H_C may be caused by the bombardment of the recoiled ions with high energy.

IV. CONCLUSION

The energy of the recoiled ions E_R from the target plane was related to the change of V_s . E_R was very different among the sputtering gases. For Ar, E_R was in the range of 200 to 380 eV. For Kr and Xe, E_R was in the range from 40 to 110 eV. The bombardment by the high energy recoiled ions changed the electrical and magnetic properties of the Fe films. The Fe films with good soft magnetism such as $4\pi M_s$ of about 21.5 kG and H_C of 5 Oe were deposited at V_s of 1200 V for Ar. For the Fe films deposited by Kr and Xe sputtering, $4\pi M_s$ and H_C were about 20 kG, and 10–30 Oe, respectively. The Fe films with lower H_C was obtained by bombardment of the recoiled ions with the high energy.

Consequently, it was found that the recoiled ions played a very important role to deposit the good soft magnetic Fe films by ion-beam sputtering. The energy of the recoiled ions, in other words, the mass of the sputtering gas may be an important parameter to characterize the properties of the Fe films.

Thin films of Sendust (wt. 85% Fe, 10% Si, 5% Al) were deposited by rf diode and dc magnetron sputtering. The objective was the production of soft magnetic films without post deposition annealing. Films were deposited on both glass and $\text{Al}_2\text{O}_3/\text{TiC}(\text{AlTiC})$ ceramic substrate. Coercivities in the range 45 to 50 Oe for rf diode deposited and 25 to 35 Oe for dc magnetron deposited films were measured. Application of rf bias to the substrate reduced this further to 7 to 12 Oe together with a reduction in grain size. The value of magnetic flux at the surface of the sputtering target was controlled by an electromagnet and found to be an important parameter for the production of soft magnetic films, low flux densities producing the softest layers. This may be related to deposition rate and/or the influence of the target magnetic field penetrating into the substrate region. The softer magnetic layers produced as a result of applying a low rf bias to the substrate is believed to be due to ion bombardment during deposition resulting in smaller grain size. © 1998 American Institute of Physics. [S0021-8979(98)41611-6]

I. INTRODUCTION

Sendust thin films have applications in both metal-in-gap (MIG) and thin film recording heads due to their soft magnetic properties and high degree of mechanical hardness. Generally, sendust films deposited by rf diode sputtering do not possess soft magnetic properties, a post-deposition anneal step being necessary to achieve a sufficiently low value of coercivity.¹ The process annealing step is normally carried out by either conventional furnace methods and/or rapid thermal annealing;² it would be a major advantage to eliminate this in production applications. In the present study, the effects of deposition parameters on magnetic properties of Sendust films have been investigated, the final objective being the optimization of process parameters in order to obtain magnetically soft films without the need for a process annealing step.

II. EXPERIMENTAL PROCEDURES

Films were produced in a CVC AST 304 sputtering system employing a 20 cm diameter, 6 mm thick Sendust target.

TABLE I. Process parameters for rf diode sputtered films.

Base pressure	$7-9 \times 10^{-7}$ Torr
Argon gas pressure	8×10^{-3} Torr
RF input power	750 W
Target/substrate separation	55 mm
Substrate temperature	10–30 °C
Deposition rate	500 nm/h
Coercivity	55–90 Oe
Grain size	55–80 nm

Rf diode sputtered films of Sendust 2–2.2 μm thick were deposited on both glass and AlTiC substrates which were thermally anchored to the substrate holder's cooling mechanism. Process conditions and parameters are shown in Table I. Dc magnetron sputtered films were produced using a 20 cm, 6 mm thick Sendust target and a backing assembly employing an electromagnet which was designed and con-

FIG. 1. Flux produced by the electromagnet as a function of applied current.

TABLE II. Process parameters for dc magnetron sputtered films.

Base pressure	$7-9 \times 10^{-7}$ Torr
Argon gas pressure	8×10^{-3} Torr
DC input power	750 W

Deposition rate	4 $\mu\text{m/h}$
Coercivity	25–35 Oe
Grain size	25–50 nm

structed in-house. By altering the coil current, the magnetic flux at the surface of the target was varied by saturating the flux within the target in the radial direction. Figure 1 shows the radial component of flux parallel to and immediately above the target surface as a function of the distance from the outer edge of the target for various coil currents.

For certain experiments, rf bias was applied to the substrates. The crystalline structure of films were characterized using x-ray diffraction (XRD). Grain size and surface roughness measurements were carried out using atomic force microscopy (AFM). Magnetic properties of films were studied using a BH hysteresis loop tracer and a magneto-optical looper utilizing the longitudinal Kerr effect. Electron microprobe analysis was used to determine the composition of films.

III. RESULTS AND DISCUSSION

A. Rf diode sputtered films

As shown in Table I, deposited layers had measured coercivities in the range 45–50 Oe, grain size varying between 60–80 nm. Film adhesion was good. Low coercivity films could only be produced from rf sputtered layers by post-deposition annealing. Deposition rates were low as expected from an rf diode configuration. These results are similar to those quoted in the literature, and verify the effect of high energy secondary electrons which are produced in rf diode configurations and are known to produce high coercivity layers.³ Film structure and properties could also be affected by reflected high energy neutrals⁴ and negative ion⁵ bombardment from impurity ions which could be significant in the current experimental conditions.

TABLE III. Optimal process parameters for dc magnetron sputtered films.

Base pressure	$7-9 \times 10^{-7}$ Torr
Argon gas pressure	20×10^{-3} Torr
DC input power	250 W
Target/substrate separation	55 mm
Substrate temperature	10–13 °C
Deposition rate	1 $\mu\text{m/h}$
Coercivity	22–30 Oe
Grain size	25–40 nm

TABLE IV. Optimal process parameters for dc magnetron sputtered films plus bias power.

Base pressure	$7-9 \times 10^{-7}$ Torr
Argon gas pressure	20×10^{-3} Torr
DC input power	250 W
RF bias power	90 W
Substrate temperature	10–17 °C
Target/substrate separation	55 mm
Deposition rate	1 $\mu\text{m/h}$
Coercivity	7–12 Oe
Grain size	10–25 nm

B. Dc-magnetron films

Table II shows that coercivities in the range 25–30 Oe were typical in the case where no rf substrate bias was applied. Adhesion was good, but AFM analysis indicated large grain sizes. Variations in process parameters were investigated and it was found that a reduction in the deposition power from 750 to 250 W as shown in Table III, together with an increase in process gas pressure from 8 to 20 mTorr did result in marginally softer films. The plasma in front of the target had a “hollow cone” shape and it was observed that where it was in contact with the surface of the substrate, deposited film surfaces appeared much smoother due to smaller grain sizes which was verified by AFM measurements. In addition, a slight decrease in coercivity was observed. A more uniform distribution of plasma was achieved by applying rf bias to the substrate during deposition with a resulting smoothness of the surface of the deposited films. This resulted in a further reduction in grain size and produced films which had much improved soft magnetic properties (7–12 Oe) as shown in Table IV. Argon was the only process gas, but incorporation of N_2 has been reported to result in further reductions in coercivity.⁶ The composition of films was very close to that of the bulk sendust target. Experiments showed that the optimum value of rf bias power for soft films was in the range 90–100 W. At higher powers a marked decrease in film adhesion and an increase in coercivity was observed. The dependence of coercivity on bias power for optimum process conditions is shown in Fig. 2. Figure 3 shows the relationship between grain size and co-

FIG. 2. Effect of bias power on coercivity.

FIG. 3. Variations in coercivity as a function of grain size.

ercivity, coercivity decreasing as expected with grain size.⁷ In Figs. 4(a) and 4(b) AFM micrographs of the surfaces of two typical films are shown. Figure 4(a) shows films deposited without the application of a bias power whereas in Fig. 4(b) the bias power is present and smaller grains have been formed.

When electromagnet coil current was increased to produce flux densities of 500–600 Gauss at the target surface and a more intense confined plasma, the deposited films had a more crystalline structure as indicated by XRD analysis and were magnetically harder. The effect may be caused in the present experiments by the increased deposition rate upsetting the balance between the atom arrival and bombardment from the substrate plasma. This allows large grains to grow with increased deposition rate and hence the production of harder layers. Further work could profitably investigate the role of nitrogen which has been reported to result in further reductions in coercivity.

IV. CONCLUSIONS

The optimum process conditions and parameters for achieving soft magnetic properties without the need for annealing and/or N₂ reactive sputtering have been determined. Soft magnetic properties were found to be dependent mainly on small grain size which was achieved by the application of rf bias power during deposition. It is believed that the plasma

FIG. 4. Atomic force micrographs showing grains in (a) a hard film (b) a soft film.

induced bias provides an energy input by ion bombardment which during deposition results in reduced grain size and softer layers.

Preparation of soft magnetic films of nanocrystalline Fe–Cu–Nb–Si–B alloy by facing targets sputtering

Masahiko Naoe, Hiroaki Matsumiya, Takayuki Ichihara, and Shigeki Nakagawa

Department of Physical Electronics, Tokyo Institute of Technology, 2-12-1, O-okayama, Meguro, Tokyo 152, Japan

Soft magnetic thin films of nanocrystalline Fe–Cu–Nb–Si–B alloy were deposited using the facing targets sputtering (FTS) apparatus. It was found that the Fe–Cu–Nb–Si–B single layers thinner than 100 nm revealed good soft magnetic properties, of which the saturation magnetization $4\pi M_s$ and the relative permeability μ_r were 11.3 kG and 500, respectively. However, when these films were thicker than 100 nm, their soft magnetic properties degraded due to the perpendicular magnetic anisotropy. On the other hand, the soft magnetic properties of the post-annealed films were improved owing to the release of stress in the films. Especially, μ_r of the post-annealed films with thickness of 120 nm increased drastically up to around 6200. Furthermore, Fe–Cu–Nb–Si–B/Al multilayers revealed superior soft magnetic properties due to the magnetostatic coupling between the two ferromagnetic layers. These multilayers post-annealed at 300 °C revealed softer magnetic properties than single layers. They exhibited very low coercivity H_c of 0.63 Oe, large $4\pi M_s$ of 13.2 kG and high μ_r of 4600. © 1998 American Institute of Physics. [S0021-8979(98)41711-0]

I. INTRODUCTION

Nowadays, the very soft magnetic thin films with large saturation magnetization are required for the development of various magnetic components in new electronic devices. Therefore, amorphous magnetic alloys have been studied and they are used for many applications. Although amorphous magnetic Fe–Si–B alloys exhibit large saturation magnetization, their soft magnetic properties tend to degrade in the high-frequency range comparing with amorphous Co-based alloys. However, it has been reported that Fe–Cu–Nb–Si–B alloys exhibit excellently soft magnetic properties and large saturation magnetization due to the formation of fine bcc Fe crystallites by adding Cu and Nb.¹ In addition, they exhibit relatively high resistivity comparing with other soft magnetic materials, such as Ni–Fe, and superior soft magnetic properties in high-frequency range. For these reasons, thin films of Fe–Cu–Nb–Si–B alloy, which are also anticipated to reveal such superior soft magnetic properties and nanocrystalline microstructure, are expected for the materials of core layers in the magnetic recording heads.

In this study, the Fe–Cu–Nb–Si–B thin films were deposited using the facing targets sputtering (FTS) apparatus at lower substrate temperature. And then, the films were post-annealed at 300 °C in order to improve the soft magnetic characteristics of them. Furthermore, the Fe–Cu–Nb–Si–B/Al multilayers were fabricated in order to improve soft magnetic characteristics of Fe–Cu–Nb–Si–B thin films with large thickness.

II. EXPERIMENT

The Fe–Cu–Nb–Si–B thin films were deposited on glass substrates at the substrate temperature T_s of 30 and 300 °C using the FTS apparatus with the targets of commercial Fe₇₅Cu₁Nb₃Si₁₄B₇ alloy under the background pressure lower than 1.0×10^{-6} Torr. The sputtering Ar gas pressure

P_{Ar} was fixed at 1.0 mTorr, and the input power P_{in} and the deposition rate R_d were set at 160 W and 4.5 nm/min, respectively. In addition, the films deposited at T_s of both 30 and 300 °C were heated at the annealing temperature T_A of 300 °C in vacuum for 2 h without the magnetic field and then, the magnetic characteristics of them were compared with those of the as-deposited films.

In addition, the Fe–Cu–Nb–Si–B/Al multilayers, as shown in Fig. 1(b), were deposited at T_s of 30 °C. Fe–Cu–Nb–Si–B layers in the multilayer were deposited under the same condition as those for the single layers, as shown in Fig. 1(a). Al layers were deposited in the same evacuated chamber at P_{in} and R_d of 180 W and 10 nm/min, respectively. The thickness of each Fe–Cu–Nb–Si–B layer was fixed at 70 nm, and the thickness of Al intermedialayer t_{Al} was changed in the range from 0 to 10 nm. And then, these multilayers were post-annealed under the same condition as those of single layers.

The crystallographic characteristics of these films were evaluated by x-ray diffractometry (XRD). The magnetic characteristics of these films, such as the saturation magnetization $4\pi M_s$ and the coercivity H_c were determined on the M – H hysteresis loops measured by the vibrating sample magnetometer (VSM). The relative permeability μ_r was measured by shunt core method at frequency of 1.0 MHz.

III. RESULTS AND DISCUSSION

A. Fe–Cu–Nb–Si–B single layers

Figure 2 shows the XRD diagrams of the Fe–Cu–Nb–Si–B single layers deposited at T_s of 30 and 300 °C, and the ones post-annealed at T_A of 300 °C, respectively. These diagrams of three kinds of films had weak peak corresponding to bcc Fe crystallites, of which the grain size was estimated to be 2–3 nm. This suggests that relatively high temperature process had little effects to the growth of Fe grains, which

FIG. 1. Schematic illustration of (a) single layer and (b) multilayer.

seem to be uniformly dispersed in these films. Figures 3 and 4 show the dependence of H_c and μ_r on the film thickness t_F for the Fe-Cu-Nb-Si-B single layers deposited at T_s of 30 and 300 °C, and the ones post-annealed at T_A of 300 °C, respectively. These characteristics were measured along the hard axis of the films. It was found that Fe-Cu-Nb-Si-B single layers as-deposited at T_s of both 30 and 300 °C thinner than 100 nm exhibited low H_c and high μ_r , of which the values of the layers as-deposited at 30 °C were 1.84 Oe and 500, respectively. However, when these films were thicker than 100 nm, their soft magnetic properties degraded drastically, so that H_c and μ_r were 40 Oe and 90, respectively. This degradation seems to be originated from the difficulty of the magnetization reversal by the appearance of perpendicular magnetic anisotropy, which is observed in the evaporated thick Ni-Fe films.² In addition, there were not any significant differences for this tendency between the films deposited at T_s of 30 and 300 °C. This result indicates that the T_s of 300 °C should not be high enough to change the microstructure of the films during deposition.

On the other hand, the soft magnetic properties of the films with t_F of 90–120 nm were improved drastically by post-annealing. Especially, the films with t_F of 100 nm deposited at 30 °C exhibited low H_c of 1.05 Oe and extremely high μ_r of 6200. The improvement of the characteristics by post-annealing seems to be originated from the release of the internal stress in the films, which makes it ease to reverse the magnetization vector in the films.

FIG. 2. X-ray diffraction diagrams of Fe-Cu-Nb-Si-B single layers deposited at T_s of 30 and 300 °C, and ones post-annealed at T_A of 300 °C.FIG. 3. t_F dependence of H_c of Fe-Cu-Nb-Si-B single layers.

B. Fe-Cu-Nb-Si-B/Al Multilayers

Figure 5 shows the dependence of H_c and μ_r on the thickness of Al layer t_{Al} for Fe-Cu-Nb-Si-B/Al multilayers deposited at T_s of 30 °C, where the film with t_{Al} of 0 nm

FIG. 4. t_F dependence of μ_r of Fe-Cu-Nb-Si-B single layers.

FIG. 5. t_{Al} dependence of μ_r and H_c of Fe-Cu-Nb-Si-B/Al multilayers deposited at T_s of 30 °C.

corresponds to the 140 nm-thick single layer as shown in Fig. 1(a). The multilayers constructed by inserting Al intermedialayer with thickness thicker than 2 nm revealed much softer magnetic properties than the thicker single layers. For example, the as-deposited films with t_{Al} of 10 nm exhibited low H_c of 2.1 Oe and high μ_r of 410, of which the value were same as those of as-deposited single layers thinner than 100 nm. These results indicate that the appearance of the perpendicular anisotropy in the ferromagnetic layer was suppressed by insertion of Al intermedialayer and that the soft magnetic characteristics were improved because of the magnetostatic coupling between the two ferromagnetic layers.

Furthermore, the soft magnetic properties of these multilayers were improved by the post-annealing process, as found for single layers. Especially, μ_r increased up to 4600

and H_c attained at the value as very low as 0.63 Oe for the multilayers with t_{Al} of 2 nm.

IV. CONCLUSIONS

Nanocrystalline Fe-Cu-Nb-Si-B thin films were deposited using the FTS apparatus. As a result, it was found that Fe-Cu-Nb-Si-B single layers thinner than 100 nm deposited at T_s of 30 and 300 °C exhibited relatively large $4\pi M_s$ of 11.3 kG and high μ_r of 500. However, when these films became thicker than 100 nm, their soft magnetic properties degraded drastically.

On the other hand, μ_r of the films thinner than 120 nm post-annealed at T_A of 300 °C were improved drastically. Especially the films with t_F of 100 nm deposited at 30 °C revealed extremely high μ_r of 6200.

In addition, the soft magnetic characteristics of Fe-Cu-Nb-Si-B/Al multilayers were improved drastically up to the same value as the single layers thinner than 100 nm. Furthermore the post-annealed multilayers exhibited very lower H_c and higher μ_r of 0.63 Oe and 4600, respectively.

Therefore, these films with such excellently soft magnetic properties seem to be suitable for the core layers in the magnetic recording heads.

Measurement of the magnetostriction constants of amorphous thin films on kapton substrates

C. Ouyang, T. W. Kim, and R. J. Gambino^{a)}

Department of Materials Science and Engineering, SUNY at Stony Brook, Stony Brook, New York 11794

C. Jahnes

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

The saturation magnetostriction constants of thin films of amorphous $\text{Co}_{39}\text{Ni}_{31}\text{Fe}_8\text{Si}_8\text{B}_{14}$ and CoZrTb have been measured either by the small angle magnetization rotation (SAMR) method or by the initial susceptibility method. The SAMR method is used for the soft materials. When the material is magnetically hard or has a strong perpendicular anisotropy, the initial susceptibility method is used. It is found that the amorphous $\text{Co}_{39}\text{Ni}_{31}\text{Fe}_8\text{Si}_8\text{B}_{14}$ prepared by ion beam deposition from an alloy target shows very soft magnetic properties and has a very small negative saturation magnetostriction, λ_s , of -1×10^{-7} . Sputtered films of CoZrTb show a strong perpendicular anisotropy when the concentration of Tb is high. We have found that the SAMR method can be applied to CoZrTb films when the Tb content is low. The saturation magnetostriction constant of a sputtered film of $\text{Co}_{78.4}\text{Zr}_{20.8}\text{Tb}_{0.8}$ is 2×10^6 . When the Tb content is high, however, the initial susceptibility method is used to measure magnetostriction. © 1998 American Institute of Physics. [S0021-8979(98)18311-1]

I. INTRODUCTION

The saturation magnetostriction constant of amorphous thin films has been measured by the capacitance method.¹ However, this method is usually used to measure the magnetostriction of the thin film on a hard substrate like glass. The film and substrate form a bimorph, so the deflection of the sample in an applied field is measured and is used to obtain the magnetostriction constant. Clearly, this method is not practical for thin film samples on soft substrates like kapton. As shown in this article, the alternative indirect measurement method, small angle magnetization rotation (SAMR)² can be used for soft thin films such as $\text{Co}_{39}\text{Ni}_{31}\text{Fe}_8\text{Si}_8\text{B}_{14}$ which have a very small magnetostriction constant. Films of CoZrTb amorphous alloy are not always soft. When the Tb content is not too high, the SAMR method can still be used to measure the saturation magnetostriction constants. When the content of Tb is high, however, the magnetostriction constants were measured using a magneto-elastic technique, the initial susceptibility method.

II. THEORY

The theory of the methods are introduced briefly here. Consider a ribbon with a tensile stress applied parallel to the ribbon axis, subjected simultaneously to a small ac magnetic field (H_{\perp}) perpendicular to the sample axis but in the plane of the ribbon and a high strength dc field (H_{\parallel}) parallel to the sample axis. The dc bias field H_{\parallel} is high enough that the sample is in the saturated state. Hence a vibration of the magnetization vector is induced about the dc field direction in the sample. The magnetization rotation produces an induced voltage e_{2f} in a sensing coil around the sample

$$e_{2f} = -4\pi NS \times d(M_s \cos \theta)/dt, \quad (1)$$

where N is the number of turns of the sense coil, S is the cross sectional area of the ribbon sample, M_s is the saturation magnetization of the sample, and θ is the angle between the magnetization and the ribbon axis. The magnetization oscillates in the plane of the ribbon around the direction of the dc bias field. The magnetization rotation angle is derived by minimizing the total energy of the sample.

$$\sin \theta = H_{\perp} / (H_{\parallel} + H_k + H_s), \quad (2)$$

where H_k is the stress induced anisotropy field, and H_s is the shape anisotropy field. The magnetocrystalline anisotropy and growth induced anisotropy fields are assumed to be very small compared to H_k and H_s . When a uniform external stress σ is applied, the signal e_{1f} changes. If the change of e_{2f} is compensated by changing the parallel field H_{\parallel} , then λ_s can be calculated from the value of ΔH_{\parallel} using the relation

$$\lambda_s = \Delta H_{\parallel} M_s / (3\sigma). \quad (3)$$

Similar to the above analysis, the SAMR method is extended to measure the saturation magnetostriction constant of amorphous magnetic thin films. A force is applied to the substrate and the film by means of a pulley and weight system and the stress condition of the film is analyzed conventionally.³ The magnitude of the stress is below the yield point of both the substrate and magnetic film in order to prevent irreversible deformation or fracture of the film. The condition of the film is monitored by measuring the resistivity of the thin film. It is found that the resistivity of the film does not change before and after the SAMR experiment.

By applying a ac field along the long axis of the sample and with no magnetic field applied perpendicular to the sample, the change of the initial susceptibility with stress can be calculated using the following formula:

$$\chi = -M_s^2 / (3\lambda_s \sigma), \quad (4)$$

^{a)}Electronic mail: rgambino@ccmail.sunysb.edu

FIG. 1. The output signal e_{2f} as a function of dc bias field.FIG. 2. The output signal $e_{2f}^{-1/2}$ as a function of dc bias field.

where χ is the initial susceptibility. From Eq. (4) it can be seen that the inverse of the susceptibility depends linearly on the stress with slope $(-3\lambda_s/M_s^2)$. The method is particularly suitable for hard magnetic thin films or the films with strong perpendicular anisotropy, because the method measures the saturation magnetostriction constants without saturating the sample.

The large parallel dc field and the ac field used in the SAMR method are supplied by two pairs of Helmholtz coils. Two nearly identical, flat sensing coils are put inside the middle of the dc and ac coils and are carefully matched to compensate each other when the sample is absent. Complete compensation is difficult to achieve, so a mutual inductor is connected between the ac Helmholtz coil and the sensor coil to get better compensation.⁴ The output voltage e_{2f} is detected by means of a lock-in amplifier. A frequency of 1 kHz is chosen so that the system is less susceptible to background noise, and can supply a distinguishable signal. This setup is also used for the initial susceptibility measurement.

III. SAMR MEASUREMENT OF $\text{Co}_{39}\text{Ni}_{51}\text{Fe}_8\text{Si}_8\text{B}_{14}$ THIN FILM SAMPLE

The thin film samples were prepared by ion beam sputtering of a target of composition $\text{Co}_{39}\text{Ni}_{31}\text{Fe}_8\text{Si}_8\text{B}_{14}$. This alloy has been reported to have extremely small magnetostriction and occurs in a composition region where magnetostriction is weakly dependent on composition.^{5,6} The thickness of the film is 0.5 μm on a kapton substrate, with thickness 75 μm , supplied by the DuPont company. Figures 1 and 2 are the graphs of e_{2f} and $e_{2f}^{-1/2}$ against the dc bias field H_{\parallel} . The relation between signal e_{2f} and tensile stress σ was measured as shown in Fig. 3. It shows that the signal increases with increasing tensile stress which implies that the saturation magnetostriction constant is negative in the sample.

In Fig. 4, the perpendicular ac magnetic field H_{\perp} and the signal output e_{2f} are kept unchanged by varying the applied stress with respect to the dc bias field. The magnetostriction

constant, as determined using Eq. (3), is -1×10^{-7} . The Young's modulus of the kapton substrate was obtained from the DuPont company and it is $2.62 \times 10^5 \text{ N/cm}^2$. The Young's modulus of the thin film is one parameter that is very difficult to determine. It has been determined for some amorphous ribbon samples.⁷ The Young's modulus of amorphous film here is approximated as $1.7 \times 10^7 \text{ N/cm}^2$.

IV. SATURATION MAGNETOSTRICTION MEASUREMENT OF CoZrTb THIN FILMS

The CoZrTb thin films were investigated following a similar procedure. The Tb is a rare earth (RE) metal and the Zr element was incorporated in order to obtain a well defined amorphous state even for low RE concentration.

In the present experiment, the amorphous transition metal-rare earth (TM-RE) CoZrTb thin films are prepared using facing target magnetron sputtering from composite targets. Film composition was determined using energy disper-

FIG. 4. The induced anisotropy field as a function of the applied stress.

sive x-ray (EDX) analysis. It has been shown that, when the composition of Tb is high, in spite of their amorphous structure, the films can exhibit an anisotropy perpendicular to their plane. If the magnetization is sufficiently low, the lowest energy orientation for the magnetization is perpendicular to the film plane.⁸ The origins of this perpendicular anisotropy have been the subject of a number of investigations. Short-range pair ordering,⁹ single-ion anisotropy produced by non-*s*-state rareearth ions,¹⁰ stress-induced anisotropies produced during the growth process,¹¹ and atomic scale structural anisotropy¹² have all been suggested as playing a role. However, if only a small amount of Tb is alloyed with the CoZr, the easy axis is in plane and the SAMR is applicable. By measuring the change of anisotropy field as a function of the applied stresses, the saturation magnetostriction constant of the $\text{Co}_{78.4}\text{Zr}_{20.8}\text{Tb}_{0.8}$ thin film is obtained by the SAMR measurement and it is found to be 2×10^{-6} .

Using the initial susceptibility method, the data in Fig. 5 are obtained for a film of composition $\text{Co}_{77.2}\text{Zr}_{20.4}\text{Tb}_{2.4}$. The saturation magnetostriction constant measured for this composition is 6×10^{-6} . What is important is that the magnitude of the magnetic field has to be controlled in the linear range of the in-plane $M-H$ curve. It is assumed that, in this linear range, the magnetization process is reversible.

One important factor which determines if the material is hard or soft is the coercivity. The coercivity is greatly affected by the roughness of the substrates. Although the kap-

FIG. 5. The inverse of the susceptibility as a function of the stress.

ton substrate provides an easy way to apply the stress to the film, at the same time, a compromise has to be made with respect to substrate roughness. The roughness of the kapton is higher than that of glass by about an order of magnitude.

The saturation magnetostriction of amorphous $\text{Co}_{39}\text{Ni}_{31}\text{Fe}_8\text{Si}_8\text{B}_{14}$ and CoZrTb thin films is measured either by the SAMR or by the initial susceptibility methods. The saturation magnetostriction constants of $\text{Co}_{39}\text{Ni}_{31}\text{Fe}_8\text{Si}_8\text{B}_{14}$, $\text{Co}_{78.4}\text{Zr}_{20.8}\text{Tb}_{0.8}$, and $\text{Co}_{77.2}\text{Zr}_{20.4}\text{Tb}_{2.4}$ thin films are -1×10^{-7} , 2×10^{-6} , and 6×10^{-6} , respectively.

Longitudinal-transverse resonance and localization related to the random anisotropy in *a*-CoTbZr films

G. Suran^{a)} and E. Boumaiz

Laboratoire Louis Néel CNRS BP 166, 38042 Grenoble, France

The properties of a resonance mode, the existence of which is related to the random local anisotropy of the sample, are reported. It was detected in amorphous CoZrTb thin films of low Tb content, in which there exists an in-plane uniaxial anisotropy field. Here the angular dependence of the mode is shown. In agreement with theory, it changes from a pure longitudinal to a mixed longitudinal transverse and a pure transverse state as a function of the orientation of the external field. The process is accompanied by the development of a very pronounced Anderson localization process due to the high value of the Tb related local anisotropy K_l . © 1998 American Institute of Physics. [S0021-8979(98)18411-6]

Theoretical calculations¹ predicted that a ferromagnet which possesses a random magnetic anisotropy should exhibit a resonance mode (RAR for random anisotropy resonance) specific to this state.

Very recently we reported that in CoZr rare earth (RE) amorphous thin films^{2,3} a resonance mode with completely new properties can be detected, apart from the so-called uniform resonance (UR). The theoretical computation showed that for a given configuration a longitudinal resonance mode should be observed, while in a crystalline material only a transverse resonance can be excited. The first period of our investigations was devoted to the demonstration that for certain configurations of the external dc field H and of the microwave field h_{rf} this new resonance mode presents a pure longitudinal character so that it is a RAR mode.

Here we report the variations of the properties of the RAR when the field H is rotated from the longitudinal to the transverse configuration. These measurements showed that in conformity with the theory the nature of the RAR mode changes and progressively takes up a transverse character. The variations of the RAR are accompanied by a very spectacular Anderson-type localization process, which is the first direct experimental observation in magnetism of this type of process.

The RAR mode was detected in amorphous $\text{Co}_{93-x}(\text{RE})_x\text{Zr}_7$ thin films. The films were prepared by rf sputtering. The mode could be observed for RE=Nd, Pr, Dy, and Tb and for $0 < x < 4$. For this small RE substitution the films possess a rather high $4\pi M_s$ and a small coercive field. The results presented here are those obtained for RE=Tb. A necessary condition for the observation of the RAR mode is that the films display a very well defined in-plane uniaxial anisotropy H_k with a negligible skew. H_k , having a magnitude of $50 < H_k < 150$ Oe, was induced during the deposition of the films by applying a dc field parallel to the film plane. Other details were reported in Refs. 2 and 3. The ferromagnetic resonance measurements (FMR) were made with a standard spectrometer at 9.8 GHz.

In the previous investigations the properties of the RAR mode were presented for the configurations which corre-

spond to the pure longitudinal resonance. This was the case when H was applied in the plane (P) defined by H_k and the film normal n , and h_{rf} was applied along H_k ($\alpha=0^\circ$) and for H in the plane P at any angle θ' with respect to n . The longitudinal nature of the RAR mode was formally demonstrated, since it could be excited for the theoretical configuration, i.e., when $H \parallel h_{rf} \parallel M_s$ and at various working frequencies. These experiments showed also that, contrary to the UR which is a collective process in which all spins participate, only a limited number of spins contribute to the RAR. This fact made it possible to explain both the small intensity of the RAR mode as compared to the UR one, and the result that the resonance field and linewidth related to the RAR mode are wholly independent of the angle θ' . This last property is due to the negligible values of the demagnetizing fields involved in the RAR process.

Let us consider now the variations of the RAR and the UR when the direction of H is changed by angle θ in the plane perpendicular to both P and the film plane, and the microwave field h_{rf} is applied in the film plane along H_k ($\alpha=0$). The results obtained on a typical sample are presented in Figs. 1 and 2. The properties of the UR are consistent with the classical models. The value of $4\pi M_s$, computed from the resonance fields in perpendicular ($\theta=0^\circ$ or H_\perp) and parallel ($\theta=90^\circ$ or H_\parallel) configuration, agree well with static measurements. The resonance field is maximal and minimal for H_\perp and H_\parallel , respectively, and for intermediate values of θ it follows the theoretical curve established for the resonance field of the UR (Fig. 2). The resonance linewidth ΔH_0 increases with increasing Tb content in the film.² ΔH_0 is of the same order of magnitude for H_\perp and H_\parallel and exhibits a well defined maxima for an intermediate value of θ . Such a behavior is archetypal for ΔH_0 of UR in thin films and is attributed mainly to geometrical effects.⁴

The variations with θ of the resonance field related to the RAR mode are opposite to that of the UR (Fig. 2): It is minimal for H_\perp and maximal for H_\parallel . The variations of the linewidth, the shape, and the intensity of the RAR mode are also specific. For $\theta=0^\circ$ the resonance field H_r and linewidth ΔH_r were minimal and the intensity I_r of the mode was maximal. The shape of the line is very close to a Lorentzian one. When θ is increased both H_r and ΔH_r increase fairly

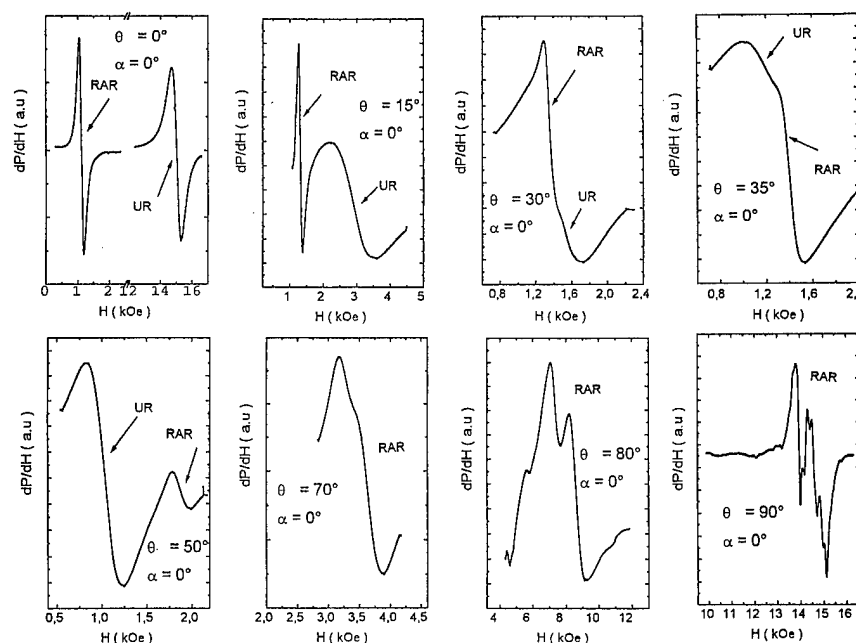

FIG. 1. Spectra of the the uniform (UR) and the random anisotropy resonance (RAR) modes at various angles θ . For $\theta \geq 70^\circ$ only the RAR mode is reported.

spectra. This process is most pronounced when $\theta=90^\circ$. In this case the spread of the spectra is the greatest and extends from $H_r \sim 9-11$ kOe up to $H_r \sim 14.5-15.5$ kOe. The intensity of the individual peaks is the smallest and their line-widths are in the range of 150–300 Oe. The results reported here correspond to a film of composition $x=1.6$ but this type of data was observed for a large number of samples.

The present results can be explained using the following assumptions: (a) the direction of H_k displays a dominant role as only those clusters (or group of spins) can participate in the RAR mode that have their easy local axis K_l oriented sufficiently close to H_k . (b) The magnetic state is determined by the ferromagnetic correlation length which is specific to a ferromagnetic thin film which possess a H_k .⁵ Such a film exhibits longitudinal and transverse ferromagnetic correlation lengths proportional to the exchange forces and a transverse magnetostatic field, respectively, so the coupling length, when no field is applied, is an order of magnitude bigger along the transverse direction than along the longitudinal one.⁵

Using these hypotheses, the variations can be explained as follows: for $\theta=0^\circ$, as shown by the previous studies, an RAR which is purely longitudinal is detected. When the external field is rotated perpendicular to the plane P , a transverse component is developed, the magnitude of which changes as a function of θ .⁶ It is fairly small for relatively small values of θ , increases when θ increases, and becomes predominant for sufficiently high θ . The fact that each mode has both longitudinal and transverse components allows to explain the variations versus θ of the resonance field H_r and of the linewidth ΔH_r . In conformity with theoretical computations, H_r is much bigger for the transverse than for the longitudinal case, which explains the increases of H_r when θ , and so the transverse component of the mode, increases. The relaxation process which corresponds to the two configura-

FIG. 2. Variations, as a function of θ , of the resonance fields related to the UR (■) and the RAR (▼) mode, respectively. (—): computed curve. (I): spread of the RAR spectra.

tions differs also in accordance with the present results: it is much stronger for the transverse case.⁷ The variations of the transverse ferromagnetic correlation length, which decreases continuously as H_r increases, is at the origin of the localization process. This localization changes from a weak to a very strong one as H_r is increased. Now the wavelength of the excited modes is limited by the volume of the ferromagnetically correlated regions, which diminishes when H_r is increased. This process makes it possible to explain the splitting of the mode into several modes. For $\theta=90^\circ$ the transverse correlation length is the smallest, the various peaks are spinwaves excited at the level of clusters, and their very short wavelength is controlled by the ferromagnetic correlation length. The configuration $\theta=90^\circ$ obviously corresponds to the pure transverse case, because the applied field H is perpendicular to the plane P which defined the pure longitudinal one. The high value of H_r and the strong localization process are due to the high value of K_l related to Tb. In conformity with the theoretical computations the transverse resonance should occur for¹

$$\omega/\gamma = H + K_l/M_s. \quad (1)$$

If one takes for $H \sim 14\text{--}15$ kOe one finds for K_l about $(1\text{--}3) \times 10^7$ erg/cm³, a result which agrees well with that obtained previously.⁸ Another series of studies, only briefly discussed here, confirmed the as proposed mechanism. It consists of investigating the variations of the spectra as a function of α while θ is kept constant. As one increased α from 0° to 90° , both H_r and ΔH_r decreased. Simultaneously the intensity of the mode diminished and finally became undetectable for a critical value of α , i.e., α_{crit} . These variations of H_r and ΔH_r are due to the progressive suppression of the transverse component of the RAR which recovers its longitudinal character. The range of α for which the mode can be detected presents spectacular variations as one approaches the pure transverse configuration. Now α_{crit} becomes fairly small so the propagation of the RAR mode is highly directional. This means that, for example, when $\theta=80^\circ$ the mode can be detected for $|\alpha| < 2^\circ\text{--}4^\circ$ and at $\theta=90^\circ$ for $|\alpha| < 1^\circ\text{--}2^\circ$. This effect results from the very important localization process as the angle along which the propagation is permitted is fairly small.

It is very instructive to study the variations of the spectra versus α at the angle θ for which the UR and RAR modes exhibit the same resonance fields (Fig. 3). It occurs for $30^\circ < \theta < 33^\circ$. For $\alpha=0^\circ$ a single, strongly distorted resonance line is detected and the related linewidth is minimum. As α is increased the overall linewidth of the mode increases and becomes maximum for $\alpha=90^\circ$, while its shape tends toward a Lorentzian one. This result confirms that when h_{rf} is oriented along H_k , only a part of the spins follow the RAR process, while all the spins contribute practically to the UR when the nonresonant condition ($\alpha=90^\circ$) for the RAR mode is settled down.

In conclusion, in amorphous thin films, apart from the UR, if the film exhibits an in-plane uniaxial anisotropy field a resonance mode is detected, the properties of which are

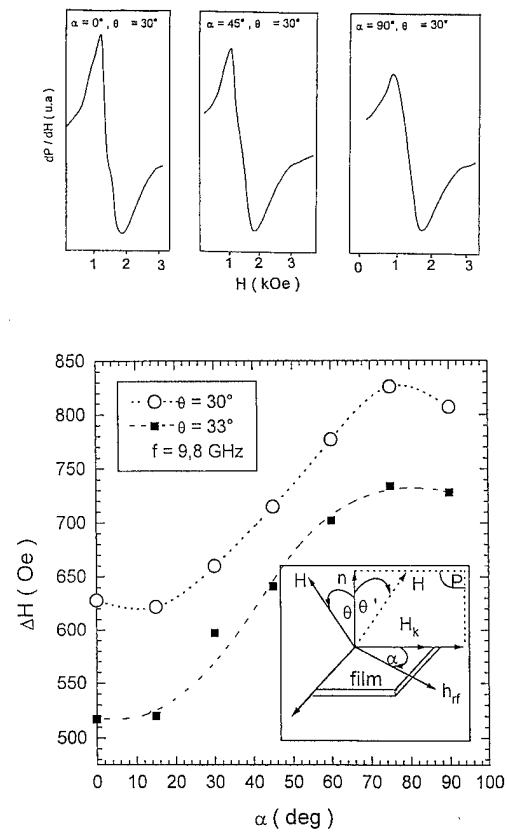

FIG. 3. Variations of the overall linewidth of the spectra as a function of α for $\theta=30^\circ$ and $\theta=33^\circ$, respectively. The definition of the various angles is in the inset.

determined by K_l . The necessity of H_k is related to the basic mechanism involved in the RAR process. The computation was based on the hypothesis that the static equilibrium axis must vary in space due to the disorder. This effect has been simulated by a spin-space rotation angle as a dynamical variable in the equations of motion. The present results, and calculations reported elsewhere, show that this angle can be a dynamical variable only for spins whose local axis is oriented sufficiently close to h_{rf} . The existence of H_k is necessary in order to obtain an RAR mode which has a sufficiently strong intensity. H_k arises from an anisotropic distribution of the local easy axis. So the number of clusters which participate in the RAR is much higher when h_{rf} is directed along the easy axis H_k as compared to the isotropic case.

Influence of barrier impurities on the magnetoresistance in ferromagnetic tunnel junctions

R. Jansen and J. S. Moodera

Francis Bitter Magnet Laboratory, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

The effect of barrier impurity atoms on the magnetoresistance of ferromagnetic tunnel junctions has been investigated. For that purpose, $\text{Co}/\text{Al}_2\text{O}_3/\text{Ni}_{80}\text{Fe}_{20}$ junctions were prepared with submonolayer amounts of Co, Pd, Cu, or Ni incorporated into the middle of the insulating oxide. The junction magnetoresistance (JMR) was measured at 77 and 300 K and referenced to that of simultaneously prepared control junctions without impurities. The JMR decays approximately linearly with increasing impurity content, the slope depending sensitively on the type of element. The decrease is most pronounced for Ni, with the normalized JMR going down at a rate of 0.39 \AA^{-1} of material (at 77 K), whereas Co shows a relatively weak decay of only 0.08 \AA^{-1} . Pd and Cu represent intermediate cases. At 300 K, the suppression of JMR is slightly higher. Results are interpreted in terms of spin-flip scattering of tunneling electrons by the impurities. © 1998 American Institute of Physics. [S0021-8979(98)17611-9]

INTRODUCTION

Tunneling of electrons between two ferromagnetic electrodes, separated by a thin insulator, is dependent on the spin orientation of the electrons. As a consequence, the resistance of a ferromagnetic tunnel junction changes when the relative orientation of the electrode magnetizations is altered, an effect already known since pioneering experiments by Julliere¹ in 1975. Large values of this so-called junction magnetoresistance (JMR), however, were only recently obtained^{2,3} and the potential for application in low-power magnetic field sensors or memory devices has been recognized.

Essential to the existence of JMR is the conservation of electron spin during the tunneling process. Indeed, barrier spin scattering has probably been one of the factors contributing to the low JMR values obtained in early attempts. Scattering of tunneling electrons by localized spins and the resulting effect on the tunnel conductance have been analyzed by Appelbaum^{4,5} and by Anderson.⁶ With respect to the JMR, the reduction due to spin scattering may be understood with the help of the following simple picture. In the absence of spin flips, the tunnel conductances G_p and G_{ap} , respectively, for parallel and antiparallel orientations of the electrode magnetizations can be written as¹

$$G_p = G(1 + P_1 P_2), \quad (1)$$

$$G_{ap} = G(1 - P_1 P_2), \quad (2)$$

where P_1 and P_2 are the electron polarizations of electrodes 1 and 2, while G is a constant. The JMR is then defined as

$$\text{JMR} = (G_p - G_{ap})/G_p. \quad (3)$$

Next consider a spin-up electron tunneling from electrode 1 to 2. When a spin-flip event occurs in the barrier, it has to enter a spin-down empty state in electrode 2. In other words, for electrons that change their spin during tunneling, it is as

if the magnetization of electrode 2 has been reversed, i.e., they exhibit an inverse magnetoresistance. Denoting their fraction by f , the conductance for parallel magnetization becomes $(1-f)G_p + fG_{ap}$ and similarly for the antiparallel case. Simple algebra then shows that the JMR is now equal to

$$\text{JMR} = \frac{(1-2f) \cdot \text{JMR}^0}{1-f \cdot \text{JMR}^0}, \quad (4)$$

where JMR^0 is the magnetoresistance in the absence of spin-flip scattering ($f=0$). In first approximation, the JMR is thus expected to go down linearly with the fraction f , since the denominator is close to unity for ferromagnetic tunneling with $\text{JMR}^0 \leq 0.3$.

High quality Al_2O_3 tunnel barriers can be prepared with great reproducibility.³ This allows us to study electron spin scattering in a systematic and controlled manner, i.e., by introducing a well-defined amount of known foreign elements into the barrier, and recording the resulting decrease of the JMR. Note that scattering at the Fermi energy is of importance here, as tunneling electrons generally originate from states in a narrow energy interval around the Fermi level. Moreover, barrier layers are usually oxides (mostly Al_2O_3) such that the incorporated impurity atoms are in an oxygen environment. Traditionally, these are studied with optical absorption, spin resonance, and Mössbauer spectroscopy. However, in the present experiment, their effect on spin-polarized transport is studied, providing an interesting comparison with the spin-scattering properties of their metallic counterparts.

In this article we present JMR measurements at 77 and 300 K for $\text{Co}/\text{Al}_2\text{O}_3/\text{Ni}_{80}\text{Fe}_{20}$ tunnel junctions with submonolayer amounts of Co, Pd, Cu, or Ni incorporated into the oxide barrier. We show that the JMR decays in a linear fashion, with the strongest decrease for Ni and only a minor

JMR reduction for Co at 77 K. Results are discussed in terms of spin-flip scattering on the basis of the possible magnetic configurations of the impurities.

EXPERIMENT

Ferromagnetic tunnel junctions were prepared by thermal evaporation in a high vacuum system with a base pressure of 1×10^{-7} mbar. Initially, a 10 Å Si seed layer was deposited onto a 5×5 cm², liquid-nitrogen-cooled glass substrate. A total of 12 Co strips, typically 80 Å thick and 0.2 mm wide, were deposited as bottom electrodes. The tunnel barrier was then prepared as follows. First all Co strips were covered with a 7 Å thick Al film. Over one half of each Co strip, a submonolayer amount of impurities (thickness t) was then evaporated, leaving the other half uncoated. The complete structure was then overcoated with another 7 Å of Al. Thus, half of each Co strip has a total of 14 Å of Al without impurities; in the other half the submonolayer of impurities is sandwiched between two 7 Å thick Al layers. Impurities are either Co, Pd, Cu, or Ni. Subsequently, the substrate was warmed to room temperature and oxidized in a glow discharge in oxygen at 7×10^{-2} mbar and a dc voltage of 1.8 kV for 110–120 s. This ensures complete transformation of all Al into Al₂O₃. After pumping down again, cross strips of the Ni₈₀Fe₂₀ top electrode (100–150 Å thick and 0.3 mm wide) are deposited at room temperature. For each individual Co bottom strip, three Ni₈₀Fe₂₀ cross strips are located in the half section that contains impurities, while three others are deposited in the part with $t=0$. For the ferromagnetic top and bottom electrodes, an in-plane magnetic field (100 Oe) was applied during growth. Film thicknesses are determined with a quartz crystal monitor with an absolute accuracy of 8%.

The prepared junctions have an area of 6×10^{-4} cm² and room temperature resistance between 1 and 25 kΩ. Magnetoresistance was measured at 77 and 300 K with an ac resistance bridge (Linear Research, LR700), using a four-terminal method.

RESULTS AND DISCUSSION

Before describing the magnetoresistance data, a few remarks about the tunneling resistance itself are appropriate. Due to the presence of incorporated foreign elements in the oxide barrier, additional transport mechanisms may be present. For example, tunneling may occur via metallic inclusions/clusters⁷ or impurity induced defect states in the barrier.⁸ If such effects are present, they should be reflected in the junction resistance, since they provide extra current channels. Also, they will contribute to a decreased JMR.⁹ For the junctions studied here, the resistance is generally comparable to that of control samples, while in extreme cases the resistance differs by no more than a factor of 2.5. This shows that the formation of the oxide barrier is not inhibited. The resistance ratio, $R_{77\text{ K}}/R_{300\text{ K}}$, is only slightly higher for some sets of impurity containing junctions, with ratios ranging from 1.2 to 1.5, compared to 1.2–1.35 for the control junctions. However, no correlation with the drop of the JMR was evident, although it may account for part of the scatter in

FIG. 1. Magnetoresistance curves for tunnel junctions containing 0.6, 1.2, and 1.8 Å of Ni, respectively, together with the corresponding control junction without Ni. Data are obtained at 77 K and the resistances are multiplied by a constant factor for each curve to have an equal value of 20 kΩ at high fields.

the JMR data presented below. Only for Co at $t=1.8$ Å was a substantially higher resistance ratio of about 1.75 found. In short, we found no major changes in the tunneling transport properties of the junctions used here, with the exception of Co at higher thickness.

As an example, magnetoresistance curves for Ni-containing junctions are presented in Fig. 1, for 0, 0.6, 1.2, and 1.8 Å of Ni, respectively. Data were obtained at 77 K and, for ease of comparison, resistances are multiplied by a constant factor for each curve to have an equal value of 20 kΩ in the high magnetic field state. We observe a significant reduction of the JMR with increasing Ni content, from 17.6% for the control junction to 13.3%, 9.6%, and 6.1%, respectively, for $t=0.6$, 1.2, and 1.8 Å of Ni. Note that the shape of the JMR curves remains practically unchanged.

Figure 2 shows JMR versus thickness t obtained at 77 K for Co, Pd, Cu, and Ni, normalized to the JMR of the corre-

FIG. 2. Normalized JMR vs thickness t of the layer of impurities present in the tunnel barrier. Data, measured at 77 K, are shown for Co (filled circles), Pd (open squares), Cu (open circles), and Ni (filled squares), together with a linear fit (solid lines).

FIG. 3. The same as Fig. 2, but measured at 300 K. For Co no linear fit is given.

sponding control junctions. Similar data acquired at 300 K are given in Fig. 3. We observe an approximately linear decrease of JMR with t , with the strongest decay for Ni (0.39 Å^{-1} at 77 K). Interestingly, for Co only a very weak suppression of the JMR is found (decay of 0.08 Å^{-1} at 77 K), while elements like Pd and Cu that are nonmagnetic in metal form have a much larger influence than Co. The same applies at 300 K, where for all materials the reduction is somewhat enhanced, most notably for Pd and Ni. Note that only in case of Co at 300 K, a clear deviation from a linear dependence is found at higher values of t . We will come back to this point below.

The linear behavior can be understood with help of Eq. (4) by assuming that, for the submonolayer thicknesses used here, the covered junction area increases linearly with t . This is a reasonable assumption considering the fact that the impurity atoms were deposited with the substrate cooled with liquid nitrogen, thereby minimizing surface diffusion and clustering effects. The net result is that the fraction f of tunneling electrons that experience a spin flip, scales linearly with t , provided that the spin-scattering properties of the impurities are not affected by the increasing interaction among the impurities at higher coverage.

Comparing different elements, the weak reduction for Co is remarkable. However, a possible explanation may be found by considering the most frequently encountered oxidation states.¹⁰ The Co^{2+} ion has a $3d^7$ electron configuration, with a corresponding spin¹¹ of $S=3/2$. The Co^{3+} ion has a $3d^6$ configuration and is generally found in a low-spin state¹⁰ with no magnetic moment, as in Al_2O_3 .^{12,13} We may therefore tentatively ascribe the weak influence of Co to the dominant presence of Co in a trivalent oxidation state. For Ni^{2+} and Ni^{3+} ions, respectively, $S=1$ and $S=1/2$ are expected¹¹ in Al_2O_3 . A magnetic moment is thus present irrespective of

the oxidation state, which would provide a qualitative explanation of the observed difference in behavior between Ni and Co.

Along the same line of reasoning, Cu is mostly found¹⁰ as Cu^+ with a nonmagnetic $3d^{10}$ closed-shell configuration (as in Cu_2O) or as Cu^{2+} with $S=1/2$ (as in CuO). It however also exists as Cu^{3+} with $S=1$ in some ternary oxides and as impurities¹¹ in Al_2O_3 . The case of Pd is a special one, since it is only known to appear in a divalent oxidation state (as in PdO), with a $4d^8$ configuration. For an octahedral oxygen coordination Hund's rules would lead to a $S=1$ state. However, for other oxygen geometries like the square planar one found in PdO , a nonmagnetic state results due to crystal field effects.¹⁰ More detailed information about the magnetic properties of Pd in Al_2O_3 is thus required.

Finally, we discuss the behavior of Co at 300 K, for which we did not find a linear relationship between JMR and t . This may be related to a change in the magnetic structure at higher Co content or to an increased interaction of the Co atoms at higher thickness. However, since also a stronger temperature dependence of the resistance was found, the faster decrease of JMR might also be caused by the presence of an additional current mechanism, such as temperature activated tunneling through Co-derived states. To clarify this, further investigations are underway.

In conclusion, the incorporation of submonolayer amounts of impurities in the barrier of ferromagnetic tunnel junctions leads to a linear decrease in the JMR. The effect is most pronounced for Ni and relatively weak for Co. The results show that tunneling magnetoresistance can be severely reduced as a result of spin scattering.

We have fabricated ferromagnet-insulator-ferromagnet tunnel junctions with Co and NiFe electrodes, where the Co electrodes are pinned with a hard magnetic $\text{Co}_{81}\text{Pt}_{19}$ alloy layer. This approach gives a coercivity of about 300 Oe for the Co layer, while that of the NiFe is about 80 Oe, so we obtain antiparallel magnetization over a wide field range. The Al_2O_3 tunneling barrier layers were formed by *in situ* plasma oxidation of elemental Al layers with thicknesses from 10 to 25 Å. For the junctions, we find room temperature magnetoresistance ratios as high as 13% and nonlinear current-voltage curves that are well fit by the Simmons tunneling theory. Depth profiling x-ray photoelectron spectroscopy of oxidized Al barrier layers on Co underlayers reveals a stoichiometry of nearly Al_2O_3 . © 1998 American Institute of Physics. [S0021-8979(98)50011-4]

I. INTRODUCTION

Recent progress in the deposition of high quality ferromagnet-insulator-ferromagnet trilayers has led to sizable spin-dependent tunneling magnetoresistance effects.¹⁻⁸ The size of the magnetoresistance makes spin-dependent tunnel junctions of interest for device applications, including magnetic random access memories and magnetic recording read heads. In order to approach the maximum achievable magnetoresistance $\Delta R/R_p = 2p_1p_2/(1-p_1p_2)$, where p_1 and p_2 are the spin polarizations of the two ferromagnetic electrodes and $\Delta R = R_a - R_p$ is the resistance difference between the antiparallel and parallel magnetization states,^{9,10} the tunnel barrier layer must be a continuous, smooth, homogeneous insulator with very clean interfaces with the ferromagnetic layers. Spin-dependent tunneling also requires a mechanism to switch between parallel and antiparallel alignment of the two ferromagnetic layers' magnetizations. Previous work has achieved antiparallel alignment of the magnetizations by choosing ferromagnetic materials with sufficiently different coercivities,¹⁻⁴ pinning with exchange anisotropy from an antiferromagnet,^{6,8} or altering the deposition temperature to create a difference in coercivities.⁵

In this article, we study the tunneling magnetoresistance effect for junctions in which we magnetically bias the bottom ferromagnetic electrode with a hard ferromagnetic layer to allow an antiparallel alignment of magnetizations on the two sides of the insulating barrier. We have fabricated $\text{Co}_{81}\text{Pt}_{19}/\text{Co}/\text{Al}_2\text{O}_3/\text{NiFe}$ spin-dependent tunnel junctions in which the hard magnetic $\text{Co}_{81}\text{Pt}_{19}$ alloy layer pins the Co layer, effectively increasing its coercivity well above that of the NiFe layer. The Al_2O_3 barrier layer is formed by expos-

ing a thin Al film, grown on the $\text{Co}_{81}\text{Pt}_{19}/\text{Co}$ bilayer, to an oxygen plasma. The junctions show nonlinear current-voltage ($I-V$) curves, indicative of tunneling across the Al_2O_3 . Our best room temperature magnetoresistance results of $\Delta R/R_p = 13\% - 16\%$, obtained for a 15–20 Å Al film oxidized for 30 s–2 min, are close to values from previous work on Co–NiFe tunnel junctions.⁴ X-ray photoelectron spectroscopy (XPS) studies of the tunneling barrier reveal nearly stoichiometric Al_2O_3 for different oxidation conditions.

II. EXPERIMENT

The tunnel junctions were deposited by dc magnetron sputtering at room temperature on Si(001) wafers with the following layer structure: Si/500 Å Pt/200 Å $\text{Co}_{81}\text{Pt}_{19}$ /200 Å Co/ Al_2O_3 /500 Å NiFe. The base pressure prior to deposition was $< 5 \times 10^{-9}$ Torr, and sputtering was done in 1.5 mTorr Ar. The $\text{Co}_{81}\text{Pt}_{19}$ layers were deposited by cosputtering from separate elemental targets. The Al_2O_3 was formed by first depositing Al films with thicknesses of 10–25 Å followed by *in situ* exposure to an oxygen plasma for durations between 30 s–10 min, at powers of 5–30 W and oxygen pressures of 23–200 mTorr. All layers were deposited prior to removing the sample from the vacuum chamber. After deposition of the structure, tunnel junctions with areas from $10 \times 20 \mu\text{m}^2$ to $50 \times 50 \mu\text{m}^2$ were patterned by standard optical lithography and wet chemical etching. The 500 Å Pt layer served as a seed layer for junction deposition as well as an unpatterned bottom electrode in the final devices. Magnetoresistance loops and $I-V$ curves were measured at room temperature using a probing station with dc current in two point geometry. Magnetic hysteresis loops were measured prior to patterning of the wafers using a vibrating sample magnetometer

(VSM) at room temperature. Also, the chemical composition of the oxide layers was examined by *ex situ* XPS with sputter etch depth profiling on samples with a Al–O layer grown on a Co film with a glass substrate and a Pt capping layer. The XPS spectra were recorded around the Al 2s, O 1s, Co 2p_{3/2}, and Pt 4f peaks.

III. RESULTS AND DISCUSSION

Figure 1 shows the magnetic hysteresis loop at room temperature for a Co–Al₂O₃–NiFe tunnel junction using a Co₈₁Pt₁₉ alloy layer to magnetically bias the Co. The magnetizations of the Co and NiFe layers reverse direction separately, with coercivities ~ 80 Oe for the NiFe and ~ 300 Oe for the Co. In the magnetic field range between these coercivities, the antiparallel alignment of the ferromagnets' magnetizations is expected to lead to a decrease in the tunneling current across the barrier and a corresponding increase in the resistance of the device.⁹ Magnetic hysteresis loops for similar Co–Al₂O₃–NiFe junctions grown without the Co₈₁Pt₁₉ layer displayed a single coercivity of ~ 20 Oe, without separate reversal of the Co and NiFe layer magnetizations. Thus, the Co₈₁Pt₁₉ layer increases the coercivity of the Co, with which it is in direct contact, as well as the coercivity of the NiFe to a lesser degree. This change from 20 to 80 Oe can be explained in terms of ferromagnetic orange peel coupling across the barrier. Cross-sectional transmission electron microscopy (TEM) images reveal a continuous Al₂O₃ barrier that is conformal with the ~ 25 Å amplitude roughness of the Co electrode. Using this roughness value along with the ~ 450 Å mean lateral size of the roughness features observed by TEM, Néel's model¹¹ for orange peel coupling gives an exchange field ~ 40 Oe. When added to the original 20 Oe NiFe coercivity, the result is comparable to the observed 80 Oe NiFe coercivity in the presence of the Co₈₁Pt₁₉.

Shown in Fig. 2(a) is the room temperature magnetoresistance curve versus applied magnetic field for a $30 \times 50 \mu\text{m}^2$ area device fabricated on a wafer with a 15 Å Al film oxidized for 30 s in 23 mTorr of oxygen with 30 W applied power. The resistance of the device as a function of

FIG. 2. (a) Room temperature resistance (R) and magnetoresistance ratio ($\Delta R/R_p$) vs applied magnetic field for tunneling between Co₈₁Pt₁₉/Co and NiFe electrodes across a Al₂O₃ barrier, formed from a plasma oxidized 15 Å Al film. Resistance was measured with a 3 mV voltage bias across the $30 \times 50 \mu\text{m}^2$ junction. (b) Tunneling current vs applied voltage (open circles) is well fit by the Simmons tunneling theory (solid line) with barrier thickness $s = 13$ Å and height $h = 3$ eV.

applied field was measured for a constant low voltage bias of 3 mV applied across the device. The maximum magnetoresistance for our devices $\Delta R/R_p \sim 13\% - 16\%$ is close to the room temperature values for previous studies of Co–Al₂O₃–NiFe spin-dependent tunnel junctions.⁴ The peaks in the magnetoresistance for this and other devices are relatively flat, indicating the presence of an antiparallel alignment of the Co and NiFe magnetizations over a wide applied field range due to the Co₈₁Pt₁₉ hard biasing layer. Figure 2(b) shows the results of an I – V measurement at zero applied magnetic field for this device. The nonlinear shape of the curve is characteristic of electron tunneling as the method of conduction across the barrier layer. A fit of this curve to the form given by the Simmons tunneling theory [Fig. 2(b), solid line] describes the data well.¹² The thickness parameter resulting from the fit is around ~ 13 Å, in reasonable agreement with the thickness of the original 15 Å Al film for the barrier, and the barrier height given by the fit of ~ 3 eV is consistent with typical values for Al₂O₃ tunnel junction barriers.^{2,4}

We have investigated the junction area dependence of the tunneling conductance at zero applied field and low voltage bias for devices from this wafer with nominal junction areas of 30×30 , 30×50 , and $50 \times 50 \mu\text{m}^2$. The devices were all located close to each other on the wafer. The conductance increases linearly with area as expected, indicating that electrons tunnel uniformly over the area of the junction. The line extrapolates to zero conductance at a finite, nonzero junction area, indicating an offset between the nominal and actual junction areas, likely due to an undercut of the junction stack from the chemical etch step during lithography.

We used *ex situ* XPS with sputter etching to investigate the chemical composition depth profile of plasma oxidized Al layers, capped with 20 Å Pt, grown on 200 Å Co underlayers on glass substrates. We discuss the results for two samples, each with 20 Å Al originally deposited and oxidized for 1 and 5 min in 23 mTorr oxygen with 30 W applied power. Tunnel junctions on a similarly prepared 1 min oxidized wafer showed tunneling magnetoresistance up to 12%,

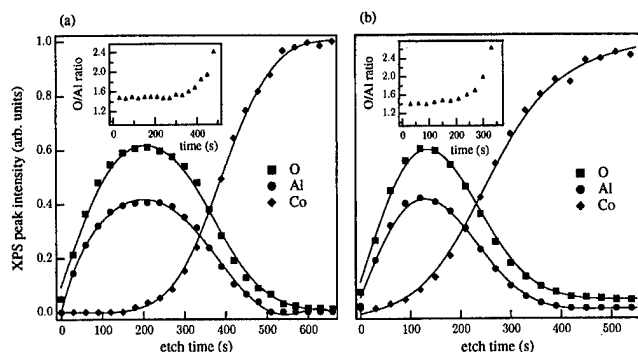

FIG. 3. XPS intensities vs depth profile sputter etch time for Al 2s (circles), O 1s (squares), and Co 2p_{3/2} (diamonds) peaks for 20 Å Al films, grown on 200 Å Co underlayers and capped with 20 Å Pt, oxidized for (a) 5 and (b) 1 min. Similarly prepared 1 min oxidized tunnel junctions displayed up to 12% tunneling magnetoresistance, and 5 min oxidized junctions showed no magnetoresistance. Inset: The ratio of atomic percent O to Al vs etch time indicates the stoichiometry of the oxidized Al layer is nearly Al₂O₃ for both 5 and 1 min oxidized samples through the majority of the oxidized Al layer.

while junctions on a 5 min oxidized wafer displayed no magnetoresistance. Figures 3(a) and 3(b) show the development of the XPS peak integrated intensities with etch time for the 5 and 1 min oxidized samples, respectively. The Pt 4f intensity from the capping layer decreases rapidly, while the Al 2s (circles) and O 1s (squares) intensities first increase and then decrease. The Co 2p_{3/2} intensity (diamonds) increases after etching through the majority of the oxidized Al layer. The ratio of O to Al atomic percent [Figs. 3(a) and 3(b), insets] is calculated by first normalizing the observed peak intensities using tabulated O 1s and Al 2s XPS sensitivities. The solid lines in Fig. 3 are guides to the eye, and there is a slight difference between Figs. 3(a) and 3(b) in etch times required to profile all the layers. For both samples, the oxidized Al layer stoichiometry is within a few percent of the desired Al₂O₃, with the exception of the initial etch step (when oxygen contamination is removed from the surface) and a tail of excess O that extends a few Å into the Co region. This residual oxygen tail could result in part from sputter yield differences between Al and O for the etch process.

The tunneling magnetoresistance is typically sensitive to oxidation time for a given thickness of Al. The magnetoresistance will decrease with either over oxidation of the barrier, leading to formation of Co-oxide at the interface with the bottom Co electrode, or underoxidation, leaving a layer of pure Al at this interface.^{1,4} XPS energy resolution is typically sufficient to detect the ~1 to 2 eV energy shift in an element's spectrum due to formation of a chemical bond in a compound versus the pure element, making this technique useful to search for an oxidized Co or unoxidized Al layer. For both samples, we detect a single Al peak, corresponding to Al₂O₃, through the thickness of the barrier. We observe a shoulder on the high energy side of the Co 2p_{3/2} peak, as expected for formation of CoO¹³ and consistent with the observed oxygen tail [Figs. 3(a) and 3(b)]. For the 1 and 5 min oxidized samples, we fit the spectra in the Co 2p_{3/2} energy region using separate Gaussian peaks for Co and CoO, offset by ~2 eV in position. The 5 min oxidized sample displays a

slightly more prominent CoO peak, relative to the Co, than the 1 min oxidized sample at the start of the Co layer. This effect is consistent with the decreased magnetoresistance in the 5 min oxidized sample compared to the 1 min oxidized sample. Thus, we conclude from the XPS data that the stoichiometry of the barrier layers is very nearly Al₂O₃ as desired, with increased CoO formation at longer oxidation time leading to decreased magnetoresistance.

IV. CONCLUSION

We have fabricated Co/Al₂O₃/NiFe spin-dependent tunnel junctions using a hard magnetic Co₈₁Pt₁₉ alloy to bias the Co layer coercivity well above that of the NiFe layer. With this approach, we can achieve antiparallel alignment of the Co and NiFe magnetizations over a wide range of applied magnetic field. The coercivity of the NiFe is affected by ferromagnetic orange peel coupling across the tunnel barrier. The tunnel barrier layers are formed by exposing a thin layer of elemental Al on top of the Co and Co₈₁Pt₁₉ layers to an oxygen plasma. The junctions show nonlinear *I*-*V* curves well described by the tunneling model and spin-dependent tunneling magnetoresistances as large as 13%. The conductance of the junctions, measured at low applied voltage bias, depends linearly on the junction area as expected. Depth profiling XPS measurements indicate that the insulating barrier layers have nearly the correct Al₂O₃ stoichiometry for a range of plasma oxidation times. The utilization of a hard magnetic layer to bias one of the ferromagnetic electrodes offers a new technique for switching between parallel and antiparallel alignment of magnetizations in the tunnel junction.

Picotesla field sensor design using spin-dependent tunneling devices

Mark Tondra,^{a)} James M. Daughton, Dexin Wang, Russell S. Beech, Anita Fink, and John A. Taylor

Nonvolatile Electronics, 11409 Valley View Rd., Eden Prairie, Minnesota 55344

Pinned spin-dependent tunneling devices were fabricated and tested in a mode suited for low-field sensing. The basic structure of the devices was NiFeCo125/Al₂O₃25/CoFe70/Ru9/CoFe70/FeMn125 (in Å). This structure had a tunneling resistivity of 110 MΩ μm² and exhibited a 20% magnetoresistance when a field was swept along the easy direction of the soft electrode. High sensitivity, low hysteresis operation was achieved by applying a bias field orthogonal to the easy axis. A sensitivity of 3%/Oe with negligible hysteresis was observed using this mode of operation. A sensor using this type of material was designed to achieve a minimum resolvable field in the picotesla range. The sensor consists of a bridge with four elements, each having 16 tunnel junctions in series. A signal-to-noise ratio of 1:1 at 1 pT (10⁻⁸ Oe) is possible assuming achievable values for the tunneling resistivity, device size, bias level, and sensitivity. © 1998 American Institute of Physics. [S0021-8979(98)52611-4]

I. INTRODUCTION

Tunneling devices have been used for many years as a way to study spin polarization in ferromagnetic thin films.¹⁻³ Typically, the experiments were carried out at low temperature since one of the electrodes was superconducting Al. Sizeable room temperature tunneling magnetoresistance in similar structures was first reported in 1995 by Moodera⁴ and Miyazaki,⁵ though that of Ref. 5 was overstated due to non-uniform current distribution effects.⁶ These recent reports demonstrated the utility of spin dependent tunneling (SDT) structures for a number of practical applications. Several papers have been published discussing their use in magnetoresistive memory and read head applications.⁷⁻⁹ The present work shows results from recently constructed SDT elements which are designed to be used in a low magnetic field sensor.

Data from these elements show about 20% junction magnetoresistance (JMR) at room temperature. When these elements are operated in a special orthogonally biased mode, they have 3%/Oe sensitivity with little hysteresis and a bipolar linear response (excellent for low field sensing). A general calculation of the minimum detectable field for a given element sensitivity is given, showing that the signal-to-noise ratio of an N -element array of SDT devices goes as \sqrt{N} . It is shown that 1 pT (10⁻⁸ Oe) sensitivity is achievable using these elements in a design which is practical from both a size and power standpoint. A complete sensor design applying these principles is described below, and is followed by a discussion of design tradeoffs in sensor power, size, and sensitivity.

II. SDT ELEMENT DESIGN AND FABRICATION

The material structure is NiFeCo 125/Al₂O₃ 25/CoFe 70/Ru 9/CoFe 70/FeMn 125, as shown in Fig. 1. The SDT material was deposited using rf diode sputtering. The Al₂O₃ layer was formed by reactively sputtering Al. Once the ma-

terial is deposited on 4 in. Si wafers, the SDT devices are patterned using standard semiconductor lithography techniques as described in previous work.⁸ A finished device is depicted in Fig. 2.

It is possible to achieve 25% junction magnetoresistance (JMR, defined as $\Delta V/V_{\min}$ and expressed as a percentage) at room temperature with a simpler structure (for instance, NiFeCo 125/Al₂O₃ 25/CoFe 125) as long as the two magnetic electrodes have different coercivities. However, the R vs H characteristics of such a device are not very good for sensor applications due to high hysteresis and nonlinearity. Consequently, we have incorporated an antiferromagnetic (AF) pinning mechanism (an FeMn pinned Co/Ru/Co/AF coupled sandwich) for the top electrode and an orthogonal biasing scheme for the bottom. Together, the resulting R vs. H behavior is nonhysteretic, very sensitive at zero field, and has usable linearity at zero field. The top electrode is designed to be the "hard" layer. Its magnetization remains rigidly fixed in small fields. The soft layer, whose easy axis is parallel to the pinning axis of the hard layer, is free to rotate under the influence of an applied field. The resistance response due to an applied field along the easy axis is shown in Fig. 3. These data show that the soft layer switches very quickly and uniformly. Data collected with a denser field spacing indicate that the entire switch takes place in less than

FIG. 1. Cross section of a pinned SDT device with the top electrode being a CoFe/Ru sandwich.

Side View

FIG. 2. Cross section of a lithographically patterned SDT device. The lateral dimensions can range from $2.5 \times 2.5 \mu\text{m}$ to $1 \times 1 \text{ mm}$.

100 mOe. Unfortunately, this switching is dominated by domain wall motion and is inherently noisy. A quieter, more linear mode of operation is required for a low field sensor.

It can be shown that a low dispersion film is very sensitive to magnetic fields in the easy direction when it is biased in the hard direction with a field just over the anisotropy field. Not only is the film sensitive, but it also rotates as a single domain with little or no hysteresis. When this is done to the soft layer of a pinned SDT element, the element's resistance is also very sensitive because 90° is the angle at which $dR/d\theta$ is highest.

The data in Fig. 4 were collected from a device biased in this way. The device was on the wafer, and the biasing was done with a permanent magnet positioned about 50 mm above the wafer. The magnitude of the field was about 20 Oe. The magnet was oriented such that most of the field was perpendicular to the sensitive axis, but rotated just enough so that the interlayer coupling was canceled by the easy axis component. One can see that the region near zero field has a very steep slope (3%/Oe) with minimal hysteresis. It is be-

FIG. 3. Magnetoresistive data from a pinned SDT device. The absolute voltage in the parallel state is about 60 mV. JMR is defined as $\Delta V/V_{\min}$ and expressed as a percentage. The field is being applied parallel to the direction of the pinned layer's magnetization.

FIG. 4. Magnetoresistance as a function of field for pinned SDT device with an externally applied hard axis bias. The field is being swept along the easy axis of the soft layer, and the hard layer is pinned in the negative direction, parallel to the easy axis. The dotted line, inserted as a guide to the eye, corresponds to a sensitivity of roughly 3%/Oe.

lieved that this is the highest reported sensitivity for a magnetoresistive sensor with no flux concentrators.

III. SENSOR DESIGN

This section will first develop a sensitivity calculation based on fundamental signal-to-noise considerations. In doing so it will be shown that, within the context of this work, hooking N SDT elements together to make a sensor increases the fundamental signal to noise ratio by \sqrt{N} , whether the elements are in series or in parallel. Then, reasonable values will be plugged in to determine the required sensor configuration for a given SDT material.

The noise voltage, V_n , for a single SDT element is taken as the Johnson noise for a resistor of equal value, R . It is assumed that each element will be operated at some fixed voltage, V_e . And each element has an intrinsic sensitivity, S , to an applied field with units of V/Oe.

The Johnson noise is given by

$$V_n = \sqrt{4kTR\Delta f} \text{ V rms}, \quad (1)$$

where k is the Boltzmann's constant, T is the absolute temperature in K, R is the resistance in ohms, and Δf is the noise bandwidth in Hz. Assuming a constant temperature and bandwidth, the noise of a single element may be written as

$$V_n = C\sqrt{R},$$

where

$$C = \sqrt{4kT\Delta f}. \quad (2)$$

The signal in a single element with sensitivity S , due to an applied field, H , is $V_e = SH$, so the signal-to-noise ratio for a single element is

$$S:N_1 = \frac{SH}{V_n} = \frac{SH}{C\sqrt{R}}. \quad (3)$$

The noise of N elements in series is then

$$V_n(N \text{ in series}) = C\sqrt{RN}, \quad (4)$$

while the noise of N elements in parallel is

$$V_n(N \text{ in parallel}) = C\sqrt{\frac{R}{N}}. \quad (5)$$

The signal of N elements in series is NS , while the signal from N elements in parallel is still S . So the $S:N$ ratios at a field H for N elements in series and parallel are

$$S:N_{\text{series}} = \frac{NSH}{V_n(N \text{ in series})} = \frac{NSH}{C\sqrt{RN}} = \frac{SH}{C} \sqrt{\frac{N}{R}}. \quad (6)$$

$$S:N_{\text{parallel}} = \frac{SH}{V_n(N \text{ in parallel})} = \frac{SH}{C} \sqrt{\frac{N}{R}}. \quad (7)$$

So the $S:N$ ratio of N elements increases as \sqrt{N} whether the elements are in series or in parallel. The $S:N$ ratio of one element may be calculated using the following values in Eq. (3):

$$\begin{aligned} S &= 0.02 \text{ V/Oe} \quad (20\%/Oe \text{ at } 100 \text{ mV bias voltage}), \\ H &= 1 \times 10^{-8} \text{ Oe (desired minimum detectable field,} \\ &\quad 1 \text{ pT} = 10^{-8} \text{ Oe)}, \\ \Delta f &= 1 \text{ Hz}, \\ T &= 300 \text{ K}, \\ k &= 1.38 \times 10^{-23} \text{ J/K}, \\ C &= 1.29 \times 10^{-10} \text{ V}, \\ R &= 100 \text{ } \Omega, \\ S:N_1(10^{-8} \text{ Oe}) &= 0.155. \end{aligned} \quad (8)$$

By using an array of 49 elements (7×7) the $S:N$ ratio at 10^{-8} Oe would increase by a factor of 7 to 1.05. To have a $S:N$ ratio of 10:1, roughly 5000 elements would be required. While this is a lot of elements, the area they require is still small. We have made high sensitivity SDT material with a tunnel resistivity (ρ_T) of $0.1 \text{ M}\Omega \mu\text{m}^2$. A $100 \text{ } \Omega$ device out of this material has an area of $1000 \mu\text{m}^2$ ($25 \times 40 \mu\text{m}$). An array of 5000 devices, then, requires $5 \times 10^6 \mu\text{m}^2$ or 5 mm^2 . Since each element is operating at 0.1 V with a resistance of $100 \text{ } \Omega$, each element consumes 0.1 mW for a total of 500 mW for the array.

We have designed and fabricated sensors using SDT elements in such an array. The sensor elements are arranged in a Wheatstone bridge configuration with each leg consisting of 16 elements in series for a total of 64 elements. The orthogonal biasing mode is achieved with on-chip current straps. A second set of straps are included for the purpose of setting the pinning direction of the bridge elements prior to use. This setting coil is arranged so that the field from it is in opposite directions over opposite legs of the bridge.

The pinning is set by warming the sample to just above the Néel temperature of the antiferromagnetic pinning layers and then cooling back to room temperature while passing current through the coil.

IV. DISCUSSION AND CONCLUSION

Looking at Eq. (3) it is clear that increasing the number of elements is not the only way to increase the fundamental signal-to-noise ratio. Decreasing the resistance per element will also have a square root dependence. This may be done by increasing the size of elements or by decreasing ρ_T . The lowest value we have made is $0.1 \text{ M}\Omega \mu\text{m}^2$, though $0.01 \text{ M}\Omega \mu\text{m}^2$ SDT materials appear to be achievable. There is certainly a limit to how low this parameter can go. The $0.1 \text{ M}\Omega \mu\text{m}^2$ material has a barrier of roughly $15 \text{ } \text{\AA}$, and every $2 \text{ } \text{\AA}$ thinner corresponds to roughly a factor of 10 decrease in ρ_T . But as its thickness decreases, the barrier is harder to make with no pinholes and becomes more fragile. Another practical limitation is that contact resistance will degrade the percentage signal if it is on the same order as the element barrier resistance.

Assuming a fixed voltage across each tunneling element, the power consumption increases linearly with both N and $1/\rho_T$. So signal-to-noise goes as \sqrt{P} whether the signal is being increased through more elements or lower resistivity.

While this work uses the thermal noise to calculate signal to noise ratios, preliminary results indicate some excess noise above the thermal noise in SDT devices. It is current dependent and primarily $1/f$ in nature. It is not yet clear how the excess noise varies with device shape and size, and barrier thickness. Further results will be reported as they become available.

SDT elements have been shown to have excellent prospects as transducers for low field magnetometers. The sensitivity and impedance are high enough to allow a multiple element array to be fabricated on a chip which would fit in a small standard integrated circuit package. This sensor would consume at most several hundred mW and much less if expected material improvements are made.

Ferromagnetic tunnel junctions with plasma-oxidized Al barriers and their annealing effects

M. Sato,^{a)} H. Kikuchi, and K. Kobayashi

Fujitsu Laboratories Ltd., 10-1 Morinosato-Wakamiya, Atsugi 243-0197, Japan

Cross-geometrical Ni-Fe/Co/Al-AIO/Co/Ni-Fe/Fe-Mn/Ni-Fe tunnel junctions were fabricated by magnetron sputtering. To form the insulating layer, an Al layer was reverse sputtered in an atmosphere of either oxygen or oxygen-argon mixture at low power after deposition. The oxidization time necessary to form an AIO barrier was much shorter than that by natural oxidization, lasting for only a half to a few minutes. By adding argon to oxygen, the oxidization was slowed down and high MR ratios were obtained for a wide range of time. A magnetoresistance (MR) ratio of 16% was observed in the as-deposited junction when the barrier was oxidized in oxygen plasma for 35 s. In addition, the MR ratio increased to 24% by annealing at 300 °C. In as-deposited junctions, the tunnel resistances were increased by increasing the plasma oxidization time, but the MR ratios gradually decreased. The estimated tunnel barrier width increased and the barrier height decreased with the plasma oxidization time. After annealing, the MR ratio increased only for those junctions oxidized for short times. This suggests that the remaining Al between the AIO and the Co surface plays an important role in the effects of annealing. © 1998 American Institute of Physics. [S0021-8979(98)47411-5]

I. INTRODUCTION

The tunnel resistances of ferromagnetic tunnel junctions with the structure of two ferromagnetic layers separated by a thin insulating barrier are known to change according to the relative angle of the magnetizations within the two layers.^{1,2} Such a junction could be applicable as a further generation magnetic read-head sensor, because theoretically, the magnetoresistance (MR) ratios of 20%–50% can be achieved with a low magnetic field. We fabricated ferromagnetic junctions with spin-valve-like MR properties and in which the tunnel barrier was naturally oxidized in Al for over 500 h.³ In addition, the MR ratios have been found to increase up to 24% after annealing at 300 °C.⁴ However, it takes a longer time to form a good barrier with almost no pinholes by natural oxidization, which is also affected by humidity and temperature and not so clean. Plasma oxidization is considered to be promising for fabricating barriers speedily with greater controllability than natural oxidization.⁵ In this study, we investigated the properties of ferromagnetic tunnel junctions having plasma-oxidized Al barriers and the effect of annealing upon them.

II. EXPERIMENT

Cross-geometrical spin-valve-like NiFe (171 Å)/Co(33 Å)/Al-AIO(13 Å)/Co(33 Å)/NiFe(171 Å)/FeMn(450 Å)/NiFe(86 Å) junctions were patterned by metal masks using magnetron sputtering on 4 in. Si wafers with 1 μm thermally oxidized surfaces. The bottom Ni-Fe/Co layer was the free layer, the center Al-AIO layer was the tunnel barrier layer, and the top Co/Ni-Fe layer was the pinned layer in which the magnetization was pinned to one direction by the exchange field from the Fe-Mn antiferromagnetic layer. Thin

Co layers having a larger polarization than the Ni-Fe layer were inserted to increase the MR changes. The top Ni-Fe layer was a cover layer to prevent oxidization. The argon pressure was 0.2 Pa and the incident power was about 2–3 W/cm².

The junction areas were 9×10^{-4} – 9×10^{-2} mm². To change the metal masks, the surfaces of the lower Co and the oxidized Al were exposed to the air for a few minutes. To form the insulating layer, a 13 Å Al layer was first deposited. Then, the process gas was introduced to the chamber at a pressure of 0.5 Pa, and samples were rf reverse sputtered for a few seconds to a few minutes at a power density of 0.01 W/cm². Oxygen or oxygen-argon mixtures were used for the process gas. Some of the samples were also annealed at a pressure of below 1×10^{-5} Torr at 200–350 °C for 1 h with an applied field of 1 kOe. Annealing and measurements were done repeatedly for each sample. The electrical properties were measured at room temperature by the four-probe method while applying a field of ± 100 Oe in the same direction as the magnetization of the pinned layer.

III. RESULTS AND DISCUSSION

Figure 1 shows the dependence of tunnel resistivity on the plasma oxidization time. The process gas used was pure oxygen. The tunnel resistances increased rapidly with an increase of plasma oxidization time. This indicates that as oxidization progresses with time, the barrier gets thicker. Though a few hundreds of hours were necessary to achieve a tunnel resistivity of 10 Ω mm² in our previous work,⁴ only about 1 min is necessary to achieve the same value.

Figure 2 shows the dependence of the barrier width and height on the plasma oxidization time. The barrier width and height were estimated by fitting the nonlinear voltage-current characteristics to the Simmons' equation.⁶ The fitting was done over the voltage range of below about 200 mV in

^{a)}Electronic mail: satoma@flab.fujitsu.co.jp

FIG. 1. Dependence of tunnel resistivity on plasma oxidation time. The thickness of the Al layer was fixed at 13 Å and the processed gas was pure oxygen.

the magnetic field of 150 Oe, which value is enough to align the magnetizations. Though the fitted values have a little spread, there are tendencies for the barrier widths to increase and for the barrier heights to decrease with the oxidation time. For the junctions with the barrier oxidized for 120 s, the barrier width is much thicker than the deposited Al thickness. Though the Al layer is thickened by oxidizing, the surface of the Co layer is probably oxidized in such samples.

MR changes were observed in almost all samples. Figure 3 shows the dependence of the MR ratio on the plasma oxidation time. The MR ratios gradually decreased when increasing oxidation time. The maximum MR ratio for an as-deposited junction was 16% achieved by plasma oxidizing for 35 s, which is a much shorter time than that required by natural oxidation. We believe that the barriers with almost no pinholes are formed by plasma oxidation.

Figure 4 shows the dependence of the MR ratios for different oxidation times on the annealing temperature. The values of the same samples, which were repeatedly annealed, are expressed in the same symbols connected by lines. In samples in which the barrier was oxidized for 35 s in pure oxygen plasma, the MR ratio increased by annealing at 300 °C. But, in the samples having barriers oxidized for 45 s, the MR ratio increased at 250 °C. In the samples having

FIG. 3. Dependence of MR ratio on oxygen plasma oxidation time. Open circles show the as-deposited values and the closed triangles show the values after annealing at 300 °C for 1 h.

barriers oxidized for over 60 s, the as-deposited MR ratios vanished by annealing at only 200 °C. In Fig. 4(a) there is a dip at 250 °C. The reason for this dip is still not clear, but it can be seen in some samples. The MR ratios after being

FIG. 4. Dependence of MR ratios for different oxidation times in oxygen plasma on annealing temperature. The values of the same samples which were repeatedly annealed are expressed in the same symbols connected by lines.

FIG. 2. Evaluated barrier width and height as related to plasma oxidation time in oxygen. Fittings for I-V curves in magnetic field according to Simmons' equation.

FIG. 5. Dependence of tunnel resistivity on the ratio of oxygen to argon. The plasma oxidation time was fixed at 90 s.

annealed at 300 °C for 1 h are also shown in Fig. 3. The MR ratios of the junctions with oxidation times of under 60 s increase and those with oxidation times of over 60 s decrease by annealing.

This is assumed to occur due to the following mechanism. In samples with oxidation times of under 60 s, the Al layer is gradually oxidized from the surface, and the bottom of the layer still remains unoxidized. In these samples, oxygen atoms at the Co surface move into the Al layer by annealing, and the polarization of electrons at the interface of Co and Al increases. In long oxidation times of over 60 s, however, the whole Al layer and the inside of the Co layer become oxidized. In these samples, the oxygen atoms at the Co surface move into the Co layer and reduce the polarization of electrons in the Co layer, therefore, disturbing the spin-preserved tunneling.

Figure 5 shows the dependence of tunnel resistivity on the ratio of oxygen to argon. The plasma oxidation time was fixed at 90 s. The tunnel resistivity rapidly decreases by adding a little argon to the oxygen. Figure 6 shows the dependence of the MR ratios of the junctions after being annealed at 300 °C for 1 h on the plasma oxidation time. The process gases for oxidation are pure oxygen and an oxygen-argon mixture at a ratio of 1:5. Pure oxygen plasma

FIG. 6. Dependence of MR ratios of junctions after being annealed at 300 °C for 1 h. The processed gases for oxidation are pure oxygen and an oxygen-argon mixture at a ratio of 1:5.

FIG. 7. MR curve of the NiFe(171 Å)/Co(33 Å)/Al-AIO(13 Å)/Co(33 Å)/NiFe(171 Å)/FeMn(450 Å)/NiFe(86 Å) junction after annealing at 300 °C for 1 h. The Al-AIO barrier layer was oxidized in oxygen plasma for 35 s.

oxidizes the Al layer so fast that the MR ratios decrease rapidly with time and it is a little hard to control. On the other hand, for the samples oxidized in the oxygen-argon mixture plasma, the oxidation was slowed down and high MR ratios were obtained for a wide range of time under 1000 s.

Figure 7 shows the MR curve of the junction after being annealed at 300 °C for 1 h and in which the barrier layer was oxidized for 35 s in oxygen plasma. The spin-valve-like MR property is clearly observed, in which the MR ratio is 24%, and its properties are almost the same as those of junctions with a naturally prolonged oxidation of the Al barrier after annealing at 300 °C.⁴

Though we expected to obtain junctions which have constant high MR ratios with better reproducibility by oxidizing in a closed chamber, the present data still have large spreads of resistances and MR ratios. These are thought to be caused by the exposure to air when the mask was changed or by the roughness of the bottom layer.

IV. CONCLUSION

We fabricated ferromagnetic tunnel junctions with barriers formed by plasma oxidation. MR ratios of 16% were observed in the as-deposited junctions with barriers oxidized in oxygen plasma for 35 s, which is a much shorter time than that needed in natural oxidation. In these samples, furthermore, the MR ratio increased to 24% by annealing at 300 °C. In the as-deposited junctions, tunnel resistances increased by increasing the plasma oxidation time, but the MR ratios gradually decreased. By adding argon to oxygen, the oxidation is slowed down and high MR ratios are obtained for a wide range of time. After annealing, the MR ratio increased only for junctions oxidized for a short time. This suggests that the remaining Al between the AIO and the Co surface plays an important role in the effects of annealing.

Tunneling magnetoresistance and current distribution effect in spin-dependent tunnel junctions

J. J. Sun,^{a)} R. C. Sousa, T. T. P. Galvão,^{b)} V. Soares, T. S. Plaskett, and P. P. Freitas^{b)}
INESC, Rua Alves Redol 9-1, 1000 Lisbon, Portugal

In this paper, spin-dependent tunnel junctions fabricated by shadow mask (junction area 0.25 mm^2) and by lithography (junction area down to $9 \times 2 \mu\text{m}^2$) were studied. The junctions have NiFe and CoFe electrodes and the insulating barrier Al_2O_3 is formed by depositing a $10\text{--}30 \text{ \AA}$ thick Al layer, followed by a 1–3 min plasma oxidation in an O_2 atmosphere. The mm^2 -size junctions show tunneling magnetoresistances (TMR) of $10\%\text{--}13.5\%$ at room temperature (RT), with 50% decrease in TMR for a bias voltage of 220 mV. The junction resistances range from hundreds of Ω to tens of $\text{k}\Omega$. The analysis of current distribution indicates that no geometrically enhanced magnetoresistance occurs in the cross-shaped mm^2 -size junctions when the measured junction resistance is five times larger than the electrode resistance over junction area. The μm^2 -size junctions show TMR of $17\%\text{--}24\%$ at RT, independent of the junction area, and have a resistance between $90 \text{ k}\Omega$ and $1 \text{ M}\Omega$ for the $9 \times 2 \mu\text{m}^2$ size (resistance-area products of $\sim 3 \text{ M}\Omega \times \mu\text{m}^2$). The μm^2 -size junctions show 50% decrease in TMR for a bias voltage of 430 mV, and high sensitivity ($>20\%/\text{Oe}$). © 1998 American Institute of Physics. [S0021-8979(98)37111-X]

I. INTRODUCTION

Large tunneling magnetoresistances (TMR) have been recently observed at room temperature (RT) in magnetic tunnel junctions.^{1–4} The TMR signal and junction resistance depend mainly on the insulating layer quality (pinholes and defects), bottom electrode roughness, and single domain state for the ferromagnetic electrodes with high polarization. Junctions with large room temperature TMR use Al_2O_3 as insulating barrier, which is prepared by deposition of a thin Al layer followed by oxidation^{1–4} (plasma or natural oxidation). Insulating layers, like MgO , HfO_2 , and AlN , prepared by sputtering or reactive sputtering,^{5,6} normally lead to low or no TMR at RT, due to incorporation of defects in the barrier, and resulting in a strong temperature dependence of TMR. AlN barriers prepared by reacting an Al layer have been reported,⁷ but junction resistance is too low (a few hundred $\text{m}\Omega$). In this case, the junction resistance is comparable to the electrode resistance over junction area, the current flows nonuniformly through the insulating layer, leading to an enhancement of the magnetoresistance (MR) effect.⁷ For memory or head applications, TMR device resistance should not exceed a few $\text{k}\Omega$. In this paper, junctions fabricated by shadow masks and by lithography are studied, where either the bottom or top electrode is pinned to ensure single domain state for one of the electrodes. The μm -size junctions show a TMR of 24% at RT, with the lowest resistance of $90 \text{ k}\Omega$ in a $9 \times 2 \mu\text{m}^2$ size junction. The current distribution in low resistance junctions is analyzed with a finite element program to distinguish true TMR from the geometrically enhanced effect.

II. EXPERIMENTAL METHOD

Two types of junction structures were studied, where either the bottom or top ferromagnetic electrode is pinned by a TbCo ferromagnetic exchange layer. Junctions have the following structure $\text{Ta}(80 \text{ \AA})/\text{NiFe}(100 \text{ \AA})/\text{CoFe}(20 \text{ \AA})/\text{Al}_2\text{O}_3/\text{CoFe}(50 \text{ \AA})/\text{TbCo}(150 \text{ \AA})/\text{Ta}(80 \text{ \AA})$ with pinned top electrode, and the ones with pinned bottom electrode $\text{Ta}(80 \text{ \AA})/\text{Cu}(40\text{--}200 \text{ \AA})/\text{Ta}(80 \text{ \AA})/\text{NiFe}(60 \text{ \AA})/\text{TbCo}(120 \text{ \AA})/\text{NiFe}(60 \text{ \AA})/\text{CoFe}(20 \text{ \AA})/\text{Al}_2\text{O}_3/\text{CoFe}(6\text{--}20 \text{ \AA})/\text{NiFe}(120 \text{ \AA})$. The magnetic layers were deposited in a Nordiko 2000 high vacuum magnetron sputtering system with a base pressure of 5×10^{-8} Torr. An aligning field of 20 Oe was applied to induce parallel easy axis in each electrode. The Al_2O_3 barrier was formed in a different setup, depositing a thin Al layer ($10\text{--}30 \text{ \AA}$, dc magnetron sputtering, 3 mTorr, $0.25 \text{ W}/\text{cm}^2$) followed by a 1–3 min plasma oxidation ($P_{\text{O}_2} = 5 \text{ mTorr}$, $4\text{--}8 \text{ mW rf}/\text{cm}^2$). For mm^2 -size junctions, both electrodes were deposited using a shadow mask, originating nine junctions each with an area of 0.25 mm^2 . For μm^2 -size junctions, the full junction structure is deposited on a blank glass substrate, and subsequently a self-aligned microfabrication process is used to achieve junction areas down to a few μm^2 . In this process, bottom electrode dimensions are $250 \times 20 \mu\text{m}^2$ or $250 \times 125 \mu\text{m}^2$, and different top electrode dimensions, consequently different junction areas down to a few μm^2 , are defined on the same mask.

III. RESULTS AND DISCUSSION

Figure 1(a) shows the room temperature MR curve for mm^2 -size $\text{CoFe}/\text{Al}_2\text{O}_3/\text{CoFe}$ junction where the top electrode is pinned, with a TMR signal of 13.5% , and $3.17 \text{ k}\Omega$ junction resistance. The inset shows the minor loop, where only the free bottom electrode is reversing its magnetization. The junction shows 7.5 Oe coercivity (H_c) for the free bot-

^{a)}Electronic mail: jjsun@pseudo.inesc.pt

FIG. 1. Room temperature MR curves of CoFe/Al₂O₃/CoFe 0.25 mm² junctions with pinned top electrode (a) and pinned bottom electrode (b). The insets show a minor loop and the relationship of H_c and H_f with the thickness of Al layer.

tom layer and a 2.5 Oe coupling field (H_f). The field was always applied parallel to the easy axis of electrodes.

Figure 1(b) shows equivalent data for the mm²-size junction with pinned bottom electrode and 11.3% TMR signal, where only the minor loop is measured in this field range. The inset highlights the relationship between H_f and H_c of the free top electrode, and the thickness of the Al layer. As the Al thickness is increased from 12 to 30 Å, H_c decreases from 17 to 12 Oe and H_f is reduced from 8 to 3 Oe. These values are always larger than the equivalent values for junctions with pinned top electrode [in Fig. 1(a)]. The H_f value is probably related to the Néel "orange-peel" coupling due to the correlated interface roughness.

The TMR decrease with increasing bias voltage is shown in Fig. 2(a) for a junction with CoFe electrodes as described previously and in Fig. 2(b) for a junction with different electrodes (NiFe, CoFe). At very low bias voltage the TMR is constant or just decreases slightly, decreasing rapidly with higher bias. The TMR is reduced to half its initial value at about 220 mV. This strong decrease of TMR with bias voltage may indicate that the junction is not perfect. This decrease may arise from the reduction of the barrier height with increasing bias, resulting in a decrease in spin polarization of the tunneling current, as discussed by Slonczewski.⁸ Looking carefully at the distinct MR fall-off curves, the curves in Fig. 2(a) are symmetric when the bias voltage is applied in different directions (i.e., from top to bottom or from bottom to top). However, the MR fall-off curves in Fig. 2(b) are asymmetric. According to the Simmons model,⁹ the potential barrier should be asymmetric for NiFe/Al₂O₃/CoFe junctions due to the different work functions of NiFe and CoFe as indicated by the asymmetric $I-V$ curves in the inset of Fig. 2(b), thereby resulting in asymmetric fall-off curves. The effective barrier height (Φ) and effective thickness (t_{eff}) were obtained, respectively, 1.4 eV and 18 Å (deposited Al thickness $t_{\text{Al}} = 20$ Å, oxidation time 2 min) for this junction from

FIG. 2. MR fall-off curves for a pinned bottom electrode CoFe/Al₂O₃/CoFe 0.25 mm² junction (a), and a NiFe/Al₂O₃/CoFe 0.25 mm² junction (b). The $I-V$ curves are represented in the insets.

fitting $I-V$ curves to Simmons model. In the case of the CoFe/Al₂O₃/CoFe junctions with pinned bottom electrode, the potential barrier should be symmetric, which is confirmed by the symmetric $I-V$ curves in the inset of Fig. 2(a) ($\Phi = 1.3 \text{ eV}$, $t_{\text{eff}} = 22 \text{ Å}$, $t_{\text{Al}} = 25 \text{ Å}$, oxidation time 2.5 min), leading to symmetric fall-off curves. This indicates that the bias dependence of TMR may be related to the tunnel barrier characteristics. This bias dependence of TMR could also be due to the spin excitations localized at the interface between the magnetic electrodes and the tunnel barrier.¹⁰

The dependence of TMR on junction resistance is now addressed. Junction resistances ranging from hundreds of mΩ to tens of kΩ can be produced varying Al thickness and plasma oxidation conditions. When the plasma oxidation of the Al layer is carried out for a short time, the junctions have relatively small resistance or negative resistance, leading to MR values up to 80%. This is a consequence of the geometrical enhancement of the MR effect.⁷ An existing program¹¹ was adapted to analyze the current distribution in these junctions. The model consists of two electrode planes connected by 26×26 equal valued resistors. The simulated MR curves for our cross shaped 0.25 mm² junctions are plotted in Fig. 3. Resistivities of 20.8 and 26 μΩ cm were used for the CoFe and NiFe layers, and theoretical TMR values of 10% and 20% are used to compare with experimental results. It can be seen that in our junction structures the geometrical enhancement effect occurs when the measured resistance in the cross, R_M , is smaller than 200 Ω. This value is about six times the electrode resistance over the junction area (in-plane resistance). For a value of 500 mΩ, this effect causes a measured MR of 100%, while the TMR is only 10%. In the experimental data also shown in this figure, it is observed that the measured MR of 10%–13.5% for R_M values ranging from hundreds of Ω to tens of kΩ is true TMR. The inset shows the measured junction resistance R_M versus real junction resistance, R_J , as simulated from our model. It can be seen that, R_M is equal to R_J when $R_J > 200 \text{ Ω}$, smaller than

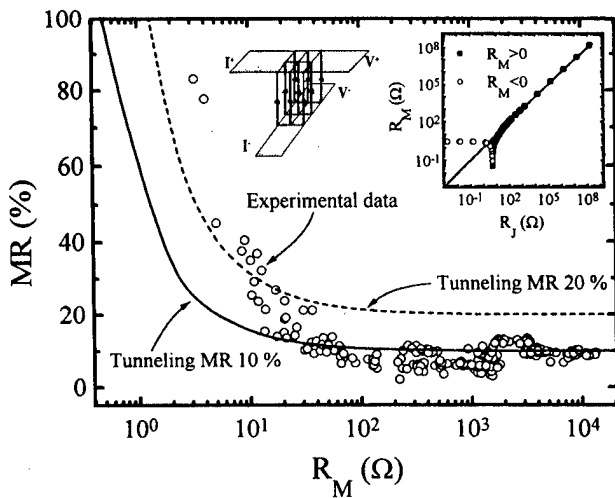

FIG. 3. Simulated MR and experimental MR data as a function of the measured resistance R_M . The inset shows the values of R_M vs junction resistance R_J resulting from the simulation. Junction area is 0.25 mm^2 .

R_J when $R_J < 200 \Omega$, and changes its sign when R_J is smaller than a few Ω , due to the inhomogeneous current flow through the insulating layer.

Figure 4(a) shows the MR curve for a CoFe/Al₂O₃/CoFe junction ($12 \times 2 \mu\text{m}^2$) with pinned top electrode fabricated by lithography. The TMR signal is 23.1% at RT, with a junction resistance of 551 k Ω . Compared with Fig. 2, an improved bias dependence of TMR is shown in the inset, where TMR drops 50% at 430 mV. These small area junctions have less defects, higher effective barrier height (2.6 eV), and smaller effective thickness (13 Å) ($t_{\text{Al}} = 15 \text{ Å}$, oxidation time 2 min). Figure 4(b) shows the MR curve of a CoFe/Al₂O₃/CoFe junction ($12 \times 2 \mu\text{m}^2$) with pinned bottom electrode, with 18.2% TMR signal at RT and 131 k Ω resistance. In both cases the easy axis is parallel to the longer dimension of the top electrode and the field is applied parallel to the easy axis.

FIG. 4. Room temperature MR curves of $12 \times 2 \mu\text{m}^2$ CoFe/Al₂O₃/CoFe junctions with pinned top electrode (a), and pinned bottom electrode (b). The inset shows the bias voltage dependence of TMR for junction (a).

FIG. 5. MR and junction resistance R_{11} vs junction area for junctions with pinned top and pinned bottom electrode fabricated by lithography.

The dependence of the TMR signal and junction resistance R_{11} (parallel state) on the junction area is shown in Fig. 5. Most junctions with sizes from 100×100 to $9 \times 2 \mu\text{m}^2$ have about 17%–24% TMR at RT with resistances from 600 Ω to 1 M Ω (resistance-area products $\alpha \sim 3 \text{ M}\Omega \times \mu\text{m}^2$). The lowest resistance for the smallest junction area ($9 \times 2 \mu\text{m}^2$) is 90 k Ω .

It is worth mentioning that the free top electrode normally has larger coercivity than the free bottom electrode, and then the MR curves for the latter show sharper switching behavior for both mm² and μm^2 size junctions ($> 20\%/Oe$ for small junctions) as shown in Figs. 1 and 4.

In conclusion, magnetic tunnel junctions with mm² and μm^2 sizes were fabricated. The mm²-size junctions show 10%–13.5% TMR at RT. The μm^2 -size junctions show 17%–24% TMR at RT, independent of the junction area, and weaker TMR dependence on bias voltage, where TMR drops 50% at 430 mV.

High conductance magnetoresistive tunnel junctions with multiply oxidized barrier

P. K. Wong, J. E. Evetts, and M. G. Blamire

Department of Materials Science, University of Cambridge, Pembroke Street, Cambridge CB2 3QZ, United Kingdom

We have fabricated $8 \times 8 \mu\text{m}^2$ mesa junctions from ultrahigh vacuum magnetron sputter-deposited Nb/Fe/Al₂O₃/Al/CoFe/Nb heterostructures. The Al₂O₃ barrier was prepared by the technique of multiple oxidation. The effect of multiple oxidation on the junction magnetoresistance (JMR) was investigated. JMR up to 6.2% at room temperature and 9.2% at 77 K was obtained. Junctions with the highest JMR have resistance-area products in the range required for device applications.

I. INTRODUCTION

Magnetoresistance in ferromagnetic tunnel junctions (MTJs), which essentially consist of an insulating tunnel barrier sandwiched between two ferromagnetic electrodes, was first observed in Fe-Ge-Fe heterostructures by Julliere,¹ who explained the magnetic field dependent tunneling conductance by a simple model relating the tunneling probability to the relative orientation of the magnetizations of the ferromagnetic electrodes. In Julliere's model, the junction magnetoresistance (JMR) at zero bias can be calculated from the electron spin polarizations of the ferromagnetic electrodes. In general, the JMR of junctions having ferromagnetic metals and/or their alloys as electrodes is predicted to have a magnitude of a few tens of percent. JMR here is defined as the maximum percentage change in junction resistance with respect to the resistance in high magnetic field. Such magnitude of JMR, together with a relatively low switching field between high and low junction resistance, make MTJ potentially applicable in sensor devices and especially in magnetic read heads.

Studies on MTJ have been focused on the fabrication of junctions having high JMR. Since JMR can be reduced by the presence of leakage current, a high quality barrier is of paramount importance. Various methods of barrier fabrication have been reported. Table I summarizes various barrier preparation methods, the corresponding resistance-area (RA) products, and the JMR of the resulting MTJ.²⁻⁷ Until recently, JMR values comparable to the predictions of Jul-

liere's model have not been observed. However Moodera *et al.*⁶ have obtained a magnetoresistance of 11.8% at room temperature and 24% at 4.2 K with CoFe/Al₂O₃/Co cross-strip junctions. JMR of 25% at room temperature has been reported recently by Parkin *et al.*⁷ in MTJ having an Al₂O₃ barrier prepared by plasma oxidation of sputter-deposited Al at room temperature. Although a high JMR comparable to the theoretical value was achieved, the RA products of the junctions were too high for device applications. It is generally easier to obtain high JMR with junctions having low leakage, i.e., high resistance. A RA product of $10^3 \Omega \mu\text{m}^2$ is required for device applications.⁸ In this article, we report a study of Fe/Al₂O₃/CoFe tunnel junctions with the barrier prepared by multiple oxidation technique. The junctions have RA products in the range suitable for device applications.

II. FABRICATION

A. Deposition of the Nb/Fe/Al₂O₃-Al/CoFe/Nb heterostructure

The Nb/Fe/Al₂O₃-Al/CoFe/Nb multilayer was deposited by ultrahigh vacuum dc magnetron sputtering in a liquid N₂ cooled chamber. The Nb layers which will be superconducting at liquid He temperature served as wiring for the accurate measurement of RA product. In the preparation of the Al₂O₃ barrier, an ≈ 1 nm Al layer was first deposited and partially oxidized in 1 kPa of O₂ for 10 min; then extra layers of about

TABLE I. Summary of the barrier preparation methods, the corresponding RA products, and the JMR values in reported work.

Barrier	Preparation method	RA product ($\Omega \mu\text{m}^2$)	JMR (Temp) (%)	Ref.
GdO _x	Oxidation in atmosphere	5×10^8	5.6(4.2 K)	2
GdO _x	Oxidation in 10^{-3} Pa during Gd deposition	1.3×10^9	7.7(4.2 K)	2
Al ₂ O ₃	Oxidation in atmosphere for 30 h	3.1×10^6	2.7(300 K)	3
Al ₂ O ₃	Oxidation in atmosphere for 24 h	6.4×10^3	18(300 K)	4

Al ₂ O ₃	Plasma oxidation of Al layer	2×10^7	25(295 K)	7
Al ₂ O ₃	Multiple oxidation technique	9.6×10^2	6.2(300 K)	This work

FIG. 1. Schematic cross section of a $8 \times 8 \mu\text{m}^2$ mesa junction fabricated from a Nb/Fe/Al₂O₃-Al/CoFeNb heterostructure.

0.1 nm Al were deposited on top and each layer was oxidized in 1 kPa of O₂ for 10 min before the deposition of others. After the deposition of the last Al layer, the barrier was oxidized in 1 kPa O₂ for 1 h. Three types of barriers, with one, three, and no extra Al layers, have been studied. A further layer of Al was deposited onto the barrier to protect it from resputtering during counter electrode deposition. A similar method has been used in superconducting tunneling device fabrication for producing a lower leakage tunnel barrier.⁹

B. Fabrication of the MTJ

In the junction fabrication process, the base circuitry including the bottom electrodes was first patterned for the entire heterostructure by standard photolithography and Ar/2% O₂ ion milling at 500 V and 0.36 mA/cm². Mesas, $8 \times 8 \mu\text{m}^2$, which defined the junction areas, were then CF₄ plasma etched into the top Nb layer using a photoresist mask, followed by ion milling the CoFe layer down to the barrier. To isolate the junction, a smaller photoresist mask was defined at the center of each of the mesas, followed by rf magnetron sputter deposition of 350 nm silica. Silica deposited onto the smaller mesa mask was later removed by dissolving the photoresist in an acetone bath, i.e., the "lift-off" process, leaving a small window in the silica layer to access the top Nb. Nb wiring 450 nm thick, was finally deposited by the lift-off process to connect the top electrode to the rest of the circuit. Figure 1 shows the cross section of a finished mesa junction.

III. MEASUREMENT

Magnetoresistance of the junctions was measured by a four-point probe inserted between a Helmholtz pair with a LN₂ insert, so that measurement can be made down to 77 K. Figure 2 shows plots of JMR against applied field for the three types of barrier. In all the three cases, the hysteretic JMR peaks occurred at about 9 mT, i.e., 90 Oe, while cohesivity of CoFe and Fe are found to be 78 Oe and 160 Oe, respectively, indicating antiferromagnetic coupling of the electrodes at the peak field. The highest measured JMR of

FIG. 2. Hysteretic MR vs H curves of the three types of samples. Peak JMR increases with the number of extra Al layers N , $N=0, 1$, and 3 .

junctions at room temperature with zero, one, and three extra Al layers were 1.4%, 2.3%, and 6.2%, respectively, with junction resistance of 3.5, 5.6, and 15 Ω measured at 4.2 K. This progressive increase in JMR and resistance with the number of extra Al layers is in agreement with a simple model in which each extra Al layer (which is much less than a monolayer) sealed a certain fraction of pinholes in the oxide barrier which are the main source of leakage current. As derived in Ref. 10, the observed JMR in a MTJ, m_{obs} is related to the junction conductance by

$$m_{\text{obs}} = \frac{m_0 G_p}{(G_p + G_l)}, \quad (1)$$

where m_0 is the maximum possible JMR of a leakage-free junction. G_p is the conductance of the leakage-free junction at the hysteretic peak field, and G_l is the leakage conductance due to the presence of pinholes which is considered to be independent of applied field. We assume that G_l is directly proportional to the total area of the pinholes. If each extra Al layer can seal a fraction a of total pinhole area in the lower layer, then for N extra Al layers,

$$G_l(N) = G_l(0)(1-a)^N. \quad (2)$$

Here $G_l(0)$ is the leakage conductance when there is no extra Al layer, i.e., when $N=0$. Substituting Eq. (2) into Eq. (1), a relation between the observed JMR, m_{obs} , and the number of extra Al layers, N , is obtained,

$$m_{\text{obs}} = \frac{m_0}{1 + \frac{G_l(0)}{G_p} (1-a)^N}. \quad (3a)$$

When $G_l(0)(1-a)^N \gg G_p$,

$$m_{\text{obs}} \approx \frac{m_0 G_p}{G_l(0)(1-a)^N} = \frac{m_0 G_p}{G_l(0)} \exp \left[N \times \ln \frac{1}{1-a} \right]. \quad (3b)$$

In Fig. 3, we present a semilogarithmic plot of m_{obs} (%) against N , as well as a plot of resistance of junctions showing highest JMR against N . The distribution of JMR for junctions with the same number of Al layers in their barriers is probably due to defects caused during the junction fabrication process. The data points with highest JMR, corre-

FIG. 3. Observed peak JMR at room temperature, m_{obs} (circles), and the resistance of junctions having highest peak JMR (squares) plotted against the number of extra Al layers N . A straight line is fitted for the samples showing highest JMR for each N , implying having best quality. The dashed line is the fitting for average JMR values.

sponding to junctions with the best quality, i.e., least defeat, lie well on a straight line of $1.400 \exp(0.496N)$. The linearity of the points indicates that $a \approx 0.39$ and $G_I(0)/G_p \gg 1$ when $N \leq 3$. In other words, each extra Al layer can seal about 39% of the total pinhole area in the lower layer. Taking the average data (dashed line in Fig. 3) also gives the same result for a . From the interception of Fig. 3, we deduced that $m_0 G_p / G_I(0) = 1.400$. To estimate the value of m_0 , the dependence of JMR on temperature must be considered. The theoretical JMR predicted by Julliere's model is 42% for a Fe-insulator-CoFe junction, which does not take into account the temperature dependence of JMR. With the temperature dependence factor 2.03 from Ref. 6, defined as the ratio between JMR at 4.2 K and at room temperature, m_0 can estimated to be equal to $42\%/2.03$, i.e., 20.7%. The JMR at 77 K in our junctions showing 6.2% magnetoresistance at room temperature ($N=3$) was found to be 9.2%, i.e., 1.5 times the value at room temperature. This ratio is similar to the temperature dependence factor between 77 K and room temperature reported in Ref. 6. Thus it is reasonable to as-

sume a value for m_0 , 20.7%, which allows us to estimate $G_p/G_I(0)$ as 0.068. Thus $G_I(0)/G_p \gg 1$ which is consistent with our assumption in the beginning of the analysis.

IV. CONCLUSIONS

We have fabricated and studied Fe/Al₂O₃/CoFe MTJ with barriers formed by a multiple oxidation technique. JMR up to 6.2% at room temperature and 9.2% at 77 K was obtained and the RA product is $9.6 \times 10^2 \Omega \mu\text{m}^2$, suitable for device applications. We have demonstrated an analysis which relates the increase in JMR with the number of extra Al layers. The model agrees well with our data. It is demonstrated that the multiple oxidation barrier preparation technique gives more control to the conductance and magnetoresistance of the MTJ which is important in applications. In particular, it allows the minimization of the unoxidized Al base layer thickness which is likely to suppress the JMR achievable.¹¹

In order to meet the requirements for applications in magnetoelectronics (e.g., read heads and magnetic random access memory), a processing scheme for micron-scale ferromagnetic tunnel junctions has been developed. A comparative study of junctions defined by shadow evaporation and by lithographic processing was made, where a similar resistance-area product of nearly $1 \text{ G}\Omega \mu\text{m}^2$ and a high tunnel magnetoresistance of up to 15% at room temperature were observed for $\text{Co}/\text{Al}_2\text{O}_3/\text{Ni}_{80}\text{Fe}_{20}$ junctions patterned by both methods. A bipolar sensor characteristic at zero field was realized by inducing anisotropies in the two ferromagnetic layers that are orthogonal to each other. © 1998 American Institute of Physics. [S0021-8979(98)50111-9]

INTRODUCTION

Spin-dependent tunneling between ferromagnetic materials has recently been generating much interest. A planar tunnel junction consists of two ferromagnetic layers separated by a thin insulating spacer layer. Changes in the relative orientation of the magnetization of the ferromagnetic films causes a resistance variation which is due to the change in the tunneling probability between the ferromagnetic electrodes. These magnetoresistance values can be considerably higher than for state-of-the-art spin valve structures.

Initially barrier properties and deposition conditions were studied using structures defined by shadow evaporation.^{1,2} This is unsuitable for integration and further miniaturization. Furthermore, as a vertical structure, microstructured tunnel junctions have a high potential in applications based on a high areal density, e.g., in high density nonvolatile solid-state magnetic memories.³

To date there have been few reports on micron-scale tunnel junctions⁴⁻⁶ although size and geometrical effects combined with intrinsic magnetic properties will strongly affect the performance of tunnel devices. Uniformity over a larger area is another key issue for further device applications. In this article tunnel junctions were patterned using a photolithographic process. The main properties will be compared with those of shadow evaporated junctions.

MULTILAYER FILM PREPARATION

The preparation of the multilayer film used in the microfabrication process has been performed by evaporation at liquid nitrogen temperatures,¹ without breaking the vacuum. On a pre-cooled glass substrate an adhesion layer of 1 nm Si was deposited. A 10 nm Co film was then deposited which later serves as the bottom electrode. During the growth of this layer a magnetic field of a few kA/m was applied to induce uniaxial magnetocrystalline anisotropy. On top of the bottom electrode an Al film was deposited; this film varied in thickness between 1.0 and 1.4 nm. The substrate was then heated to room temperature. The barrier was formed by oxidizing the Al in an oxygen dc glow discharge for 100 s at a pressure of 70 mTorr.⁷ A 17 nm thick $\text{Ni}_{80}\text{Fe}_{20}$ top electrode was deposited next. Also during the growth of this layer a magnetic field was applied to induce uniaxial magnetocrystalline anisotropy, in this case oriented perpendicular to that applied during growth of the bottom layer. Finally, the multilayer was covered by a 4 nm protective Al layer.

MICROFABRICATION PROCESS

The multilayer films were patterned using a four-mask lithographic process, as schematically illustrated in Fig. 1.

First the bottom electrode geometry was defined by Xe ion milling leaving isolated mesas containing the full multilayer stack on the glass substrate [Fig. 1(a)]. During a second ion milling step the active junction area was further defined by etching into the parts of the mesa that were not covered by resist [Fig. 1(b)]. The resulting junctions have a square geometry, ranging from 64×64 down to $2 \times 2 \mu\text{m}^2$.

^{a)}Electronic mail: boeve@imec.be

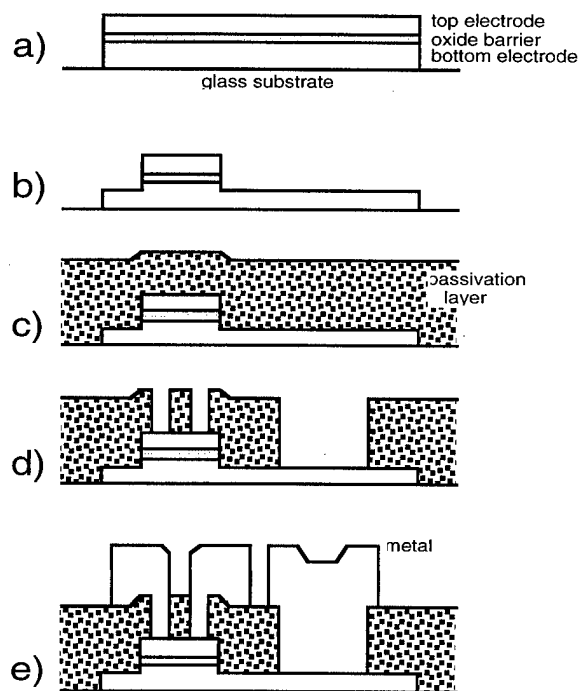

FIG. 1. Schematic of the cross section of the multilayer during microfabrication showing the different steps in the process.

The ion milling was timed to stop under the Al_2O_3 barrier. Nevertheless, some depth nonuniformity over bigger areas seems unavoidable and this can drastically increase the series resistance of the bottom electrode. The junctions were then passivated with 75 nm of Si_3N_4 followed by another lithographic step and opening of the contact holes in the nitride using a CF_4 rf plasma [Figs. 1(c) and 1(d)]. The final step consists of the deposition of a 15 nm TiW/155 nm Au metallization [Fig. 1(e)].

During the Si_3N_4 deposition the substrate temperature was raised to 250 °C, which does not allow the use of a self-aligned process, which would save one mask level and is better suited to reach the smallest dimensions.

An optical microscope image of the completed devices is shown in Figs. 2(a) and 2(b). Also visible are the well-defined top and bottom contacting schemes. In the middle of the bottom electrode two contacts are patterned in order to measure the resistance of the bottom electrode and the double top contacts for the bigger structures [Fig. 2(b) shows a $16 \times 16 \mu\text{m}^2$ junction) are used to control the nitride opening.

RESULTS AND DISCUSSION

The series resistances of the contacts were estimated by measuring the junctions with different contacting schemes. The resistance of the bottom electrode is around 100 Ω , while the resistance of the top electrode connection depends on the cross section of the via between the contact pad and the top electrode, and is generally much lower.

In order to investigate whether the processing scheme described above influences the barrier properties, $I(V)$ char-

FIG. 2. (a) Layout of the final tunnel devices. Along the sides of the main mesa, several junctions are defined, ranging from 64×64 down to $2 \times 2 \mu\text{m}^2$ for the smallest junctions. The contacts for the bottom electrode are situated in the middle of the mesa. (b) A junction of $16 \times 16 \mu\text{m}^2$ which clearly shows the double top metal contact.

acteristics were measured for several junctions having different areas and they were compared with known results of junctions defined by shadow evaporation.

Curves taken from 0 to 0.75 V show the quality of the barrier after processing. At low bias, the behavior is ohmic while at higher bias it shows a nonlinear dependence. Simmons' general theory of tunneling⁸ was used to estimate the barrier height and thickness for junctions with different areas. Independent of the original Al thickness in the sample, all junctions give a barrier height of 3 eV, while the barrier thickness varies from 1.30 to 1.36 nm. For junctions with a 1.0 nm Al layer a slight asymmetry was seen in the $I(V)$ curves which corresponds to an asymmetric barrier caused by some oxide formation in the Co bottom layer.⁹

The resistance scaled from typically 200 k Ω for a junction area of $64 \times 64 \mu\text{m}^2$ up to 14 M Ω for $4 \times 4 \mu\text{m}^2$. This leads to a resistance-area product of nearly 1 G $\Omega \mu\text{m}^2$, as represented in Fig. 3, which is in excellent agreement with previous results obtained for similar junctions prepared by shadow evaporation.

Magnetoresistance measurements at room temperature were performed in an adapted probe station. A maximum magnetic field of 8 kA/m could be applied using a set of Helmholtz coils. Generally two-point measurements were

FIG. 3. Area dependence of the junction resistance. Open symbols represent junctions made by shadow evaporation, and closed symbols represent microfabricated junctions.

done, justified by the enormous difference between the junction and possible contact resistance. Tunnel current variations due to the magnetic field were monitored by both ac and dc techniques using a SR830 lock-in amplifier and a HP4145B semiconductor parameter analyzer. Different magnetoresistance values were measured for different Al thicknesses, even though the barrier height and thickness in Simmons' model gave similar results. For the case of 1.0 nm Al, the maximum magnetoresistance value at room temperature was 14% for a $64 \times 64 \mu\text{m}^2$ junction. A thicker Al layer (1.4 nm) resulted in a lower magnetoresistance value of 10% but in this case that value has been measured for junction areas down to $4 \times 4 \mu\text{m}^2$. Compared to the smaller barrier thickness, some unoxidized Al might be left over, which would result in a decrease of spin polarization of the current from the Co electrode and therefore the lower magnetoresistance value.

The magnetoresistance curve shows a different switching behavior for both ferromagnetic layers, which is confirmed by the hysteresis loop before patterning. Figure 4 shows the magnetoresistance curves for a magnetic field applied along a different anisotropy axis. Since the Co has a higher coercivity and anisotropy field than the $\text{Ni}_{80}\text{Fe}_{20}$ layer, the full signal can only be reached along the easy axis of the Co layer. Thus, in this configuration the (nearly) antiparallel alignment of the magnetization in the ferromagnetic layers can be reached, as can be seen by the formation of a plateau on the magnetoresistance peaks. In addition, the orthogonal anisotropies create a bipolar sensor characteristic around zero field.

CONCLUSION

We have successfully patterned ferromagnetic tunnel junctions with areas ranging from 64×64 down to $4 \times 4 \mu\text{m}^2$. The properties of these are very similar to the properties of junctions prepared by shadow evaporation. The

FIG. 4. Magnetoresistance response along both the Co and the NiFe easy axes. The difference in relative height can be explained by the relative orientation of the magnetization of the ferromagnetic layers for a magnetic field being applied along a different axis.

resistance-area product of the junctions is nearly $1 \text{ G}\Omega \mu\text{m}^2$, which seems very high for further device applications.

We have started studying the effect of intrinsic magnetic properties on the performance of the tunnel junction. A bipolar sensor characteristic can be achieved by using a perpendicular anisotropy axis orientation for the different ferromagnetic layers. Further scaling towards smaller dimensions is under investigation as is the influence of the different processing steps on tunnel junction properties. Smaller dimensions will require a self-aligned processing scheme.

Nanometric cartography of tunnel current in metal-oxide junctions

V. Da Costa,^{a)} F. Bardou, C. Béal, Y. Henry, J. P. Bucher, and K. Ounadjela

Institut de Physique et Chimie des Matériaux de Strasbourg, UMR 46 CNRS, F-67037 Strasbourg Cedex, France

Recently, ferromagnet/insulator/ferromagnet trilayer junctions were shown to exhibit large magnetoresistance effects. However, these effects proved to be poorly reproducible from sample to sample. To get a nanoscopic insight on the origin of these fluctuations, we have used a combined atomic force microscope/scanning tunneling microscope setup to map the tunnel current that flows through metal/oxide stacks. The current histogram, which extends over 1–2 orders of magnitude, is found to be well described by a simple model which takes into account tiny spatial fluctuations of tunnel barrier thickness (typically, 0.1 nm). Moreover, our analysis shows that the total conductance of imperfect metal/oxide junctions tends to be dominated by very few sites. This result allows us to relate the sample-to-sample conductance fluctuations to slight local variations of the tunnel barrier parameters. © 1998 American Institute of Physics. [S0021-8979(98)47511-X]

Spin-polarized tunneling has been extensively studied since the discovery of large magnetoresistance effects in magnetic tunnel junctions (MTJ's) consisting of ferromagnet/insulator/ferromagnet trilayers.^{1,2} Because of their remarkable magnetotransport properties, these MTJ's appeared as good candidates for technological applications in devices such as magnetic sensors or nonvolatile data storage memories. The advantage of using such junctions is, however, significantly altered by the large fluctuations of tunnel resistance (up to four orders of magnitude) that are currently observed from junction to junction,^{2–5} and which make them not yet usable as industrial products. At the present time, the irreproducibility of the electrical characteristics of MTJ's is assumed to be mostly related to large changes in local electron barrier transmission, which may result from defects providing localized electron states, from fluctuations in barrier thickness, as well as from pinholes in the insulating films.^{3,5} All of these defects being normally buried within the core of the MTJ's, hence, hard to investigate, no attempt has yet been made to verify these assumptions.

One way to study the role played in the tunneling process by localized defects inside the insulating layers is to investigate, at a nanoscopic scale, the tunnel current transmitted through the insulating layers while not yet covered by the second ferromagnetic layers. For studying locally this current, we applied the technique first developed by Morita *et al.*⁶ and later improved by Houzé *et al.*⁷ for measuring local contact resistance. An atomic force microscope (AFM) equipped with a conducting tip was used to simultaneously record the usual topographical information and map the current flowing through a tunnel barrier consisting of an insulating oxide layer naturally grown on a ferromagnetic film. Our experimental results show that the tunnel current can vary from place to place by more than one order of magnitude. A statistical analysis involving a fit of the current distributions according to a simple model reveals that the large

fluctuations of current are probably induced by rather small fluctuations of tunnel barrier thickness (or of other tunnel parameters such as barrier height).

The samples studied consisted of superficially oxidized Co films. The initial films were prepared by ultrahigh vacuum e-beam evaporation. 10 nm thick hcp (0001) Co layers were first grown at room temperature on 25 nm thick single-crystal (0001) Ru buffer layers previously deposited at 700 °C on freshly cleaved mica substrates. The oxidation of the top Co surface was later accomplished by leaving the films under atmospheric conditions for three months. X-ray photoelectron spectroscopy (XPS) revealed that the average thickness of the capping oxide was (2 ± 1) nm.

The current measurements were carried out using a commercial atomic force microscope operated in a dc contact mode. The deflection of the cantilever supporting the tip, and thus the force exerted on the tip (a few 10^{-9} N), was maintained at some constant value by a feedback loop that continuously adjusted the cantilever height as the tip was scanned over the sample surface, which allowed us to determine the topography of the investigated sample. Furthermore, using a conducting tip and applying a bias voltage of, typically, 1 V between the bottom ferromagnetic electrode and the tip permitted us to record simultaneously the current flowing through the insulating layer. This led to a cartography of the electrical features of the insulator surface.

The probes were common Si_3N_4 cantilevers with integrated tips having an apex radius of, typically, 30 nm. These probes were coated with 30 nm thick conducting films deposited under high-vacuum conditions. The quality of the experimental results strongly depended on the nature of the conducting material.⁷ We obtained the best results with probes covered with TiN_x compounds, which exhibit ultrahardness, good corrosion resistance, as well as electrical conductivities comparable to those of pure transition metals.⁸ Indeed, the current images obtained with TiN_x coated probes proved to be reproducible as successive scans were performed.

Figures 1(a) and 1(b) show typical topographical and current images recorded simultaneously while exploring a

^{a)}Electronic mail: victor@michelangelo.u-strasbg.fr.

FIG. 1. (a) $136 \times 136 \text{ nm}^2$ topographical and (b) electrical images of the same area of an epitaxial Co film oxidized in air. (c) Topography profile along AA'. (d) Profile of the tunnel current intensity along BB'=AA'.

$136 \times 136 \text{ nm}^2$ region of an oxidized Co surface. The AFM image of Fig. 1(a) reveals that the oxidation in air of our Co films gives rise to a relatively flat top surface, the standard deviation of the height data being 0.5 nm within the displayed area. However, no atomic steps and terraces can be distinguished.

The currents that were measured in the different parts of the investigated region [Fig. 1(b)] range from almost zero or undetectable values to nearly 100 nA. As we checked by investigating (oxide-free) Au surfaces with the same experimental setup, currents that are measured in the case of a metal/metal contact between the tip and sample are no less than a few microamperes. Furthermore, one can check using (for example) Simmons' model⁹ that the most probable current values, which range from a few tenths of nanoampere to a few nanoamperes, are consistent with tunneling through a 1–2 nm thick barrier of height 1–2 eV and an effective contact area of about 20 nm^2 , as inferred from the size of the smallest electrical features that were imaged. Therefore, we attribute the low currents that are obtained on CoO_x films to tunneling. Moreover, no pinholes are found in the CoO_x cap (we have unambiguously observed such pinholes as we investigated other kinds of samples). Following this line of thought, the bright (respectively, dark) zones in the current image correspond to high (respectively, low) tunneling currents, and hence, to sites where the barrier thickness might be locally smaller (respectively, larger) than the average value. Notice that a comparison of the topographical [Figs. 1(a) and 1(c)] and electrical [Figs. 1(b) and 1(d)] data does not reveal a strong correlation between the two kinds of features.

The electrical images were analyzed statistically by calculating the distribution of tunnel currents $P_i(i)$. The distribution computed from the image shown in Fig. 1(b) is presented in Fig. 2. It exhibits a highly asymmetric shape with a pronounced maximum at 3 nA and a very slow decrease for large currents. From this distribution, it appears that the tunnel current varies from place to place by 1–2 orders of magnitude and that relatively high currents are only transmitted through very few sites.

These observations can be connected to the statistical

FIG. 2. Experimental and theoretical distributions of tunneling current. The experimental data were calculated from the image of Fig. 1(b).

analysis of tunneling through a barrier with fluctuating parameters presented in Ref. 10. As a simple model, one may consider a rectangular potential barrier of height V_0 and thickness l . The tunneling probability t for particles of mass M and kinetic energy $E < V_0$ is given by $t = 1/\{1 + B^{-1} \sinh^2[l/(2\lambda)]\}$ where $\lambda = \hbar/[2\sqrt{2M(V_0 - E)}]$ is the attenuation length within the barrier and $B^{-1} = V_0^2/[4E(V_0 - E)]$. To take into account the fluctuations in the barrier thickness, one may introduce a Gaussian distribution of average value l_0 and standard deviation σ . This results, for $t \ll 1$, in a log-normal distribution $P_i(t)$ of the transmission coefficient t

$$P_i(t) \approx \frac{1}{\beta\sqrt{2\pi}} \frac{1}{t} \exp\left[-\frac{1}{2\beta^2} [\ln(t) - \alpha]^2\right], \quad (1)$$

where $\alpha = \ln(4B) - l_0/\lambda$ and $\beta = \sigma/\lambda$. As shown in Ref. 10, the transmission t exhibits very different behaviors, depending on σ . For very small σ , $P_i(t)$ is close to a narrow Gaussian distribution. For larger σ , $P_i(t)$ becomes much "broader" and has a tail at large t , which allows the transmission t to fluctuate from place to place by as much as several orders of magnitude. One can show that the current may then flow so inhomogeneously through the tunnel barrier that the total transmission is dominated by very few sites. Thereby, one can predict very large sample-to-sample conductance fluctuations. Interestingly, these results are robust and similar behaviors would be obtained for non-Gaussian fluctuations of barrier thickness, more complicated barrier shapes, or fluctuations in the barrier height.

This model has been used to achieve a quantitative determination of the statistical properties of the Co/CoO_x junctions. As shown in Fig. 2, the current distribution is reasonably well fit using Eq. (1). This is remarkable since the latter contains only two parameters, α and β , and results from a simple model (rectangular barrier; Gaussian fluctuations). As currents i are measured and not directly the transmissions t , a scaling parameter η was introduced to give $t = \eta i$. This transformation, implying $P_i(i) = \eta P_i(\eta i)$, leads to an expression for the current distribution $P_i(i)$ similar to that obtained for the transmission t , the α parameter in Eq. (1) being simply replaced by $\alpha' = \alpha - \ln(\eta)$. The proportionality

factor η is related to the contact area between the tip and the sample, and hence, depends upon the tip radius, since the latter determines the size of the surface area from which the current is collected.

For all data, however, there is a small residual discrepancy between the experimental data and the distribution fit for values of i larger than 75 nA and smaller than 5 nA, which may be attributed to the finite size of the probing tip. Indeed, the rather large radius of the tip prevents access to the small holes that exist in the sample surface. One may reasonably think that in these holes the tunnel barrier is thinner and the current, which could be transmitted, is higher. Not probing them results in an underestimate of the amount of surface associated with large currents. Correspondingly, sharp asperities that would correspond to low transmissions tend to keep the tip away from the surface, thus artificially increasing the proportion of low currents. This explanation accounts for the weak correlation that exists between the surface topography and barrier thickness.

The best fit of our experimental data [Fig. 2] was obtained with $\alpha' = 3.0$ and $\beta = 1.4$. To our knowledge, no experimental value has been reported for the effective barrier height $\phi = V_0 - E$ of cobalt oxide. However, typical values of ϕ available in the literature range from 1 to 4 eV, depending on the insulating material.¹¹ This corresponds to attenuation lengths λ ranging from 0.05 to 0.1 nm. Combining these limiting values with the parameter $\beta = \sigma/\lambda$ deduced from our fit, we can estimate the variance of the barrier thickness distribution σ , to be between 0.07 and 0.14 nm. This value ($\sigma \approx 0.1$ nm) is smaller than the topographical roughness (≈ 0.5 nm). We, thus, interpret the latter as being due mostly to the underlying Co film. This film would be covered by a CoO_x layer of nearly constant thickness.

From the distribution $P_i(i)$ determined experimentally, it is concluded that the tunnel current flows in an inhomogeneous manner through the CoO_x barrier. Indeed, we calculate that 50% of the total current that gets through the barrier is transmitted by only 9% of the sample area. Concomitantly, the average transmission $\langle t \rangle$ is 15 times larger than the most probable transmission t_i , which is associated with the peak of the distribution. This shows that the usual integrated conductance or resistance measurements that yield only average values fail to characterize imperfect tunnel junctions. Indeed, for broad distributions as opposed to narrow distributions, such as Gaussian, the random variable fluctuates so much around its average value that the average value in itself ceases to be a relevant parameter.^{10,12} This statement is reinforced by the fact that our sample is a very good one from the point of view of the tunnel barrier homogeneity since fluctuations of barrier thickness amount to less than one atomic layer ($\sigma \approx 0.1$ nm). For $\sigma = 0.2$ nm ($\beta = 2.8$), which would still be good according to usual thin-film standards, 50% of the current would be transmitted through only 0.3% of the sample surface. The average transmission $\langle t \rangle$ would be 2×10^5 times the most probable transmission t_i , thus ut-

terly ruining the meaningfulness of measurement techniques yielding average values.

In conclusion, we have demonstrated the possibility of reproducibly mapping, at a nanoscopic scale the tunnel currents. As predicted in Ref. 10, the distribution of currents tends to exhibit a shape similar to that of Lévy distributions, characterized by a long tail extending to large current values. This shows that broad distributions, widely known in complex systems such as turbulent flows or spin glasses,¹² also appear in the theoretical description of simpler phenomena such as quantum tunneling through insulating layers.

Moreover, the statistical properties of these Lévy-like distributions imply dramatic practical consequences. First, for thin insulating films, very small thickness fluctuations ($\sigma = 0.1$ nm) give rise to tunnel current fluctuations greater than one order of magnitude. Second, usual measurements of average conductance performed on imperfect tunnel junctions yield incomplete information about the tunnel barrier, since the current flows in such an inhomogeneous way that the total conductance is often dominated by contributions from a few localized sites having very high transmissions. Third, the statistical properties discussed here could naturally account for the large fluctuations of integrated conductance observed from sample to sample. Finally, we can take advantage of the results of our statistical analysis to propose a strategy for making more reproducible tunnel junctions, in the same way as previously used to improve the lowest temperatures achieved by laser cooling.¹³ Apart from the trivial argument of reducing σ , Eq. (1) shows that one could drastically reduce the current fluctuations by increasing λ , i.e., using lower tunnel barriers.¹⁴

Sintered Sm₂(Co,Fe,Cu,Zr)₁₇ magnets with improved high temperature performance have been obtained by reducing the iron content in the magnet alloys. A record intrinsic coercive force, iH_C , of 8.3 kOe at 400 °C was obtained when the iron content was decreased to 7 wt%. At 400–600 °C, 2:17 magnets with low iron content have demonstrated lower irreversible loss of magnetic flux, higher maximum energy product, and lower temperature coefficient of iH_C . A temperature coefficient of $iH_C = -0.12\%/^\circ\text{C}$ (20–400 °C) was obtained for the low Fe magnets, compared to $-0.23\%/^\circ\text{C}$ for commercial 2:17. Reducing iron content increases both Curie temperature and anisotropy field. Therefore, it is anticipated that new 2:17 magnet materials capable of operating at 400 °C or higher temperatures can be developed by reducing or eliminating the iron content and making other adjustments in composition and heat treatment. © 1998 American Institute of Physics. I. INTRODUCTION

The power system in a new generation of aircraft requires magnetic materials capable of operating at temperatures higher than 400 °C. The More Electric Aircraft (MEA) initiative proposed by the U.S. Air Force is a driving force in high temperature requirements for magnetic materials. In the MEA, all hydraulic-mechanical components will be replaced by electric-magnetic components, and the centralized hydraulic heat sink will also be eliminated. This will significantly enhance the reliability, reduce maintenance, and greatly decrease support and logistics cost. However, the high temperature properties of magnetic materials must be substantially improved to satisfy MEA requirements.

The best existing high energy density, high temperature permanent magnet material, Sm₂(Co_wFe_xCu_yZr_z)₁₇ (2:17), has been satisfying many applications at temperatures up to 300 °C. For applications at temperatures higher than 400 °C, magnetic materials with improved high temperature properties must be developed. Prior to the Air Force MEA initiative, there was little demand or need for magnets capable of operation above 300 °C. Accordingly, magnet performance at temperatures $>300^\circ\text{C}$ has not been a principal concern in magnetic materials R&D. In the last 14 years, permanent magnet material R&D has been focused primarily on the following three topics: (1) Nd₂Fe₁₄B based materials and other ternary rare earth (RE)-transition metal (TM) systems; (2) New RE-TM permanent magnet materials containing interstitial atoms (N or C); and (3) New nanocrystalline composite magnet materials containing the magnetically hard phase with high crystalline anisotropy and the magnetically soft phase with high saturation magnetization.^{1–3} These ef-

forts, however, have not yet led to the next generation of rare earth permanent magnets (REPM).

Because most RE-TM binary systems have been extensively studied, it is more likely that the new promising compounds will be found in ternary or quaternary systems. Based on today's knowledge of thermodynamics, kinetics, crystallography, and magnetism, it is still impossible to predict or calculate crystalline structures and basic magnetic properties. In the foreseeable future the empirical approach will be our principal method to search for new promising compounds in more complicated systems. Therefore, it will take more time than one might expect before another breakthrough occurs. Since the appearance of Nd₂Fe₁₄B magnets in 1983, the worldwide study of 2:17 magnets has been slowed considerably. Actually, there is still room for significant improvement. We believe that, in addition to studying new materials, we can continue to improve the best existing high temperature 2:17-type magnets.

Recent studies have shown that the thermal stability of 2:17 magnets is related to the iron content in the 2:17 magnet alloys.^{4–6} In order to increase the long-term reliable operating temperature from the current 300 °C to higher temperatures, two important magnetic parameters of the existing commercial 2:17 magnets must be improved. The first one is iH_C . Our high temperature characterization of the best commercial high-coercivity-type 2:17 magnets showed that at 400 °C, iH_C dropped from the room temperature value of >30 to 5.7 kOe and the second-quadrant induction demagnetization curve is not straight.⁴ In order to keep the induction demagnetization curve a straight line, which is important for dynamic applications, iH_C at 400 °C has to be increased

FIG. 1. iH_C vs Fe content in 2:17 magnets at 400 °C.

to at least > 8 kOe. The second magnetic parameter which needs to be improved is the long-term thermal stability. Our previous application-oriented characterization showed that after aging at 400 °C for 4300 h, the maximum energy product, the best commercial 2:17 magnet, dropped as much as about 40%.⁶ Obviously, the long-term high temperature stability of the current 2:17 magnets must be significantly improved before they can be used at 400 °C or higher.

Previous studies on the $\text{Sm}_2(\text{Co}_{1-x}\text{Fe}_x)_{17}$ system indicated that when $x < 0.5$, the compound retains the easy-axis magnetic symmetry. And, on further reduction of x , both the anisotropy field and the Curie temperature are substantially increased.^{7,8} Therefore, it is possible that the above mentioned two problems can be resolved by reducing the iron content and by making other adjustments in composition and heat treatment.

II. EXPERIMENT

New 2:17 magnets with compositions of $\text{Sm}(\text{Co}_{0.9}\text{Fe}_{0.1}\text{Cu}_{0.06}\text{Zr}_{0.02})_{7.6}$ with $v = 0-0.28$ (0–20 wt%) were prepared by vacuum induction melting and conventional powder metallurgy processing. Magnetic characterizations from room temperature up to 300 °C were performed using a hysteresigraph, while magnetic properties at 400 °C and higher were determined using a vibrating sample magnetometer (VSM). Because the VSM characterization is an open-circuit measurement, careful calibration was made so that the result of VSM measurement was in excellent agreement with that of closed-circuit hysteresigraph measurement. An aging experiment was carried out up to 845 °C, in which the flux was determined using a fluxmeter. Curie temperatures of 2:17 magnets with various iron contents were determined

using thermal magnetic analysis (TMA). A Siemens Gaddis Hi Start Area Detector x-ray diffraction was used to determine lattice constants of 2:17 materials with different iron contents. Curie temperatures and lattice constants are shown in Table III.

III. RESULTS AND DISCUSSION

Figure 1 shows the iH_C versus the iron content in 2:17 magnets at 400 °C. The data show that reducing iron content enhances the iH_C at 400 °C. A record iH_C of 8.3 kOe at 400 °C was obtained when the iron content was decreased to 7 wt%. It is also significant that the second-quadrant induction demagnetization curve of this magnet is a straight line at 400 °C. Decreasing iron content in 2:17 magnet alloys also resulted in magnets with low temperature coefficient of $iH_C(\beta)$. A very low β of $-0.12\%/^{\circ}\text{C}$ (20–400 °C) was achieved in the magnets with 8 wt% iron. This is about half of the value of commercial 2:17 magnets. The 2:17 magnets with low iron content demonstrate not only higher iH_C and lower temperature coefficient of iH_C , but also greater maximum energy product $(\text{BH})_M$ at high temperatures. Table I lists the $(\text{BH})_{\text{max}}$ of three 2:17 magnets with different iron contents at different temperatures. Figure 2 shows the

FIG. 2. Energy product vs Fe content at different temperatures: solid marks-measured data, hollow marks-estimated.

FIG. 3. Room temperature magnetic flux of the magnets with different % Fe after 2 h at the temperatures shown. Sample dimensions: ϕ 1.0 cm \times 0.635 cm.

$(BH)_{\max}$ vs Fe content at different temperatures. It is evident that at high temperatures 2:17 magnets with lower iron demonstrate better magnetic performance than that of commercial 2:17. With adjustments in chemical compositions and heat treatment, further improvement is anticipated.

Figure 3 compares the magnet flux change of 2:17 magnets in an aging experiment up to 845 °C. Three 2:17 magnets with various iron contents were used in this experiment as shown in Table II. The dimensions of the samples for this experiment were 1.00 cm in diameter, and 0.635 cm in thickness. In this experiment, 2:17 magnet samples were heated to a specific temperature between room temperature and 845 °C, kept at that temperature for 2 h, cooled to room temperature, and then the magnetic flux was measured using a Helmholtz coil. It can be seen from Fig. 3 that after the short-term aging, the magnet with 15 wt% Fe retained the highest flux when aged below 400 °C. When aged between

TABLE III. T_c , lattice constants, and unit cell volumes of the 2:17 magnets.

Fe [wt%]	T_c [°C]	a [Å]	c [Å]	v [Å ³]
15	810	8.493	12.244	764.94
8 [B]	...	8.471	12.218	759.31
0	855	8.459	12.206	756.27

400° and 550 °C, the magnet with 8: wt% Fe showed the highest flux. When aged from >550 to 845 °C, the magnet with 0 wt% Fe demonstrated the highest flux. The sample with 0 wt% Fe had lower μH_C at room temperature, which might affect the losses at <550 °C.

One reason why 2:17 magnets with low iron content demonstrate improved high temperature stability is their higher Curie temperature. The Curie temperature of a 2:17 magnet with 0 wt% Fe is 855 °C, or 45 °C higher than that of a 2:17 magnet with 15 wt% Fe (Table III). We anticipate that these new 2:17 magnets with low (or zero) iron content will demonstrate improved long-term high temperature stability because of their increased Curie temperature and the increased crystalline anisotropy. Results of x-ray diffraction showed that the new 2:17 magnet materials containing 8 wt% Fe and 0 wt% Fe have rhombohedral crystalline symmetry and the crystal lattice constants shrank slightly upon reducing iron content as shown in Table III.

These new promising results show that it is possible to develop new 2:17 magnet materials capable of operating at temperatures of 400 °C or higher by reducing or eliminating the iron content and making other adjustments in composition and heat treatment.

Phase transformation and magnetic properties of $\text{Sm}(\text{Co}_{0.91-x}\text{Fe}_x\text{Cu}_{0.07}\text{Zr}_{0.02})_z$ powders for bonded magnet applications

W. Gong, B. M. Ma,^{a)} and C. O. Bounds

Rhodia, Rare Earths and Gallium, CN 7500, Cranbury, New Jersey 08512

Structural and magnetic properties of $\text{Sm}(\text{Co}_{0.91-x}\text{Fe}_x\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$, where $x = 0, 0.12, 0.21, 0.29$, and 0.32 , and $\text{Sm}(\text{Co}_{0.64}\text{Fe}_{0.28}\text{Cu}_{0.06}\text{Zr}_{0.02})_z$, where z ranged from 6.9 to 8.6 , have been systematically investigated by x-ray powder diffraction. It was found that most of these alloys exhibit a hexagonal $\text{Th}_2\text{Ni}_{17}$ structure with a space group $\text{P6}_3/\text{mmc}$ after an optimum solid solution treatment with rapid quench. The fully processed materials (after precipitation hardening) all exhibit a rhombohedral $\text{Th}_2\text{Zn}_{17}$ structure with a space group of $\text{R}\bar{3}\text{m}$ as the primary phase. For $\text{Sm}(\text{Co}_{0.91-x}\text{Fe}_x\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$, the lattice parameters, a and c , and cell volume, V , increase slightly at first with increasing x , and then more sharply when x is increased above 0.28 . The latter drastic increase in lattice parameters and cell volume results in a sharp decrease in the H_{ci} , H_c , and H_k values of fully processed materials. For $\text{Sm}(\text{Co}_{0.64}\text{Fe}_{0.28}\text{Cu}_{0.06}\text{Zr}_{0.02})_z$, the lattice parameters, a and c , and cell volume increase slightly when z is varied from 6.8 to 7.8 , then exhibit a drastic decrease when z is further increased beyond 8.0 . A B_r of 11.3 kG, H_{ci} of 27 kOe, and BH_{max} of 30 MGOe have been obtained on $\text{Sm}(\text{Co}_{0.63}\text{Fe}_{0.28}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ after a solid solution at 1160°C and aging at 850°C . © 1998 American Institute of Physics. I. INTRODUCTION

The phase transformations of $\text{Sm}(\text{Co}, \text{Fe}, \text{Cu}, \text{Zr})_z$ alloys of commercial interest have been studied by many researchers.¹⁻³ There are many models to explain the relationship between transitional phases and the mechanism, microstructure, and magnetic properties obtained on finished magnets. One model suggests that a single phase precursor (after a solid solution treatment and quenching) with a rhombohedral $\text{Th}_2\text{Zn}_{17}$ structure with a space group of $\text{R}\bar{3}\text{m}$ (Space Group No. 166) is critical to obtaining the desired final microstructure.⁴ A second model indicates that the precursor phase must be a metastable TbCu_7 structure with a space group of $\text{P6}/\text{mmm}$ (Space Group No. 191).⁵ Since both structures are metastable derivations of the CaCu_5 structure, lattice parameters and their relationship with nominal compositions are of scientific interest and technological importance.

To clarify the structural transitions, we studied a narrowly defined composition range and conducted a series of experiments with various thermal treatments to compare the structure, lattice parameters, and magnetic properties of $\text{Sm}(\text{Co}_{0.91-x}\text{Fe}_x\text{Cu}_{0.07}\text{Zr}_{0.02})_z$, where $x = 0.21$ to 0.32 and $z = 6.9$ to 8.6 . Our focus was on how the alloy composition affected the microstructural, lattice parameters, and the magnetic properties, namely B_r , H_c , H_{ci} , BH_{max} , and H_k .

II. EXPERIMENT

$\text{Sm}(\text{Co}_{0.91-x}\text{Fe}_x\text{Cu}_{0.07}\text{Zr}_{0.02})_z$, where $x = 0.21$ to 0.32 and $z = 6.9$ to 8.6 , were prepared by conventional vacuum induction melting and mold casting. Alloy ingots were solu-

tion treated over a temperature range of 1130 to 1200°C for 4 to 24 h and quenched to room temperature, precipitation hardened at 800 – 900°C for 4 to 10 h, slowly cooled to 400°C at a rate of $1^\circ\text{C}/\text{min}$, and then quenched to room temperature. Alloy ingots were pulverized by a jaw crusher and a cross-beater mill to obtain powder with top size of $75\ \mu\text{m}$. A Perkin Elmer differential thermal analyzer (DTA) was employed to determine magnetic phase transformations. A Siemens x-ray diffractometer with a $\text{Co } K\alpha$ radiation and a Hi-Star area detector were utilized to measure the lattice parameters and to determine the structure of the alloy powders. Magnets of 3 mm in diameter were prepared by mixing powders with molten paraffin, aligned under a 30 kOe peak magnetic field then solidified. The magnetic properties were determined by measuring the second quadrant demagnetization curves using a vibrating sample magnetometer (VSM). A theoretical density of $8.4\ \text{gm}/\text{cm}^3$ and a demagnetization factor of 0.29 were used to obtain the normalized $4\pi M$, B_r , and BH_{max} values of powders.

III. RESULTS AND DISCUSSION

Shown in Fig. 1 are the x-ray powder diffraction patterns of $\text{Sm}(\text{Co}_{0.69}\text{Fe}_{0.22}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ alloy quenched from solid solution treatment temperature [patterns (a) and (b)] and after an isothermal aging at 850°C [patterns (c) and (d)]. In order to obtain a more precise structural indexing, the x-ray diffraction (XRD) was performed on powder samples with and without magnetic field alignment. Diffraction patterns (a) and (b) in Fig 1 are XRD patterns of samples quenched from solid solution temperature with and without magnetic field alignment, respectively. These samples had a hexagonal $\text{Th}_2\text{Ni}_{17}$ structure with $a = 8.489$, $c = 8.176$, and $V = 510.22\ \text{\AA}^3$. The enhanced intensity of the (004) peaks for

^{a)}Electronic mail: bma@us.rhodia.com

FIG. 1. X-ray powder diffraction of $\text{Sm}(\text{Co}_{0.69}\text{Fe}_{0.22}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ after a solid solution treatment (a) without and (b) with magnetic alignment and fully processed materials (c) without and (d) with magnetic alignment.

the powder aligned with a magnetic field suggests that the alloy is magnetically anisotropic with easy magnetization direction (EMD) parallel to the c axis of the hexagonal structure. Similarly, XRD patterns (c) and (d) in Fig. 1 correspond to the patterns of fully processed powders with and without magnetic alignment, respectively. A rhombohedral $\text{Th}_2\text{Zn}_{17}$ structure with space group of $\text{P6}_3/\text{mmc}$ was identified. Again, the enhanced intensity of (006) peaks with the magnetic alignment suggests that it is magnetically anisotropic with EMD parallel to the c axis of the rhombohedral structure.

Shown in Fig. 2 are the variations of H_{ci} , B_r , H_c , BH_{\max} , and H_k of optimally processed $\text{Sm}(\text{Co}_{0.91-x}\text{Fe}_x\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ with Fe content, where $x=0.12, 0.21, 0.29$, and 0.32 . As shown, the H_{ci} remains relatively constant when the x was increased from 0.21 to 0.28 then decreases sharply when x reached values above 0.28. Unlike H_{ci} , the B_r increases linearly with the Fe content. The BH_{\max} increases initially then approaches a maximum value of nearly 30 MGOe when x was increased above 0.25. It is of interest to note that both H_c and H_k increase linearly at low Fe content then decrease sharply when the Fe content was increased beyond 0.28. The sharp decrease in H_c , H_{ci} , and H_k may result from a structural change but further study is required to be precise.

Shown in Fig. 3 are the variations of the lattice parameters, both a and c , and the cell volumes of the fully processed $\text{Sm}(\text{Co}_{0.91-x}\text{Fe}_x\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ with Fe content, where $x=0, 0.12, 0.21, 0.29$, and 0.32 . At $x=0$ (without Fe substitution), an a of 8.459 Å, c of 12.206 Å, and V of 756.27 Å³ were obtained when indexed to the $\text{Th}_2\text{Zn}_{17}$ structure. The lattice parameters, a and c , and cell volume, V , increase gradually with increasing Fe content initially. Sharp

FIG. 2. The variations of H_{ci} , B_r , BH_{\max} , H_c , and H_k of $\text{Sm}(\text{Co}_{0.91-x}\text{Fe}_x\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ with Fe content, where $x=0.12, 0.21, 0.29$, and 0.32 .

increases in a and c and V can be observed when the x was increased above 0.29. The increase in lattice parameters and cell volume may hinder atomic diffusion and the development of the desired cellular structure with appropriate precipitated phase for domain wall pinning.⁶ The increase in the lattice parameter and cell volume also stretch the distance

FIG. 3. The variations of lattice parameters a , c and cell volume V of $\text{Sm}(\text{Co}_{0.91-x}\text{Fe}_x\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ with Fe content, where $x=0, 0.12, 0.21, 0.29$, and 0.32 .

FIG. 4. The variations of H_{ci} , B_r , BH_{max} , H_c , and H_k of $\text{Sm}(\text{Co}_{0.64}\text{Fe}_{0.28}\text{Cu}_{0.06}\text{Zr}_{0.02})_z$ with z , where z ranges from 6.9 to 8.6.

between transition metals, and enhance the exchange interaction, which may explain the magnetization increase with increasing Fe content.

Shown in Fig. 4 are the variations of H_{ci} , B_r , BH_{max} , H_c and H_k of $\text{Sm}(\text{Co}_{0.64}\text{Fe}_{0.28}\text{Cu}_{0.06}\text{Zr}_{0.02})_z$, where z ranges from 6.9 to 8.6. Initially, the H_{ci} increases linearly with the stoichiometric ratio z , reaches a peak at $z=8.0$, then decreases drastically when z is increased beyond 8.0. Unlike H_{ci} , the B_r increases linearly with the z value. The BH_{max} , H_c and H_k all increase gradually with increasing z , reach a maximum at z near 8.0 to 8.2 then decrease sharply when z is increased beyond 8.2. Again, the decrease in H_{ci} and H_k may be caused by the lattice parameters and cell volume which inhibit the formation of desired microstructure.

Shown in Fig. 5 are the variations of lattice parameters, a and c , and the cell volume, V , of fully processed $\text{Sm}(\text{Co}_{0.64}\text{Fe}_{0.28}\text{Cu}_{0.06}\text{Zr}_{0.02})_z$, where z ranged from 6.9 to 8.6. The trends of the lattice parameters, a and c , and cell volume are very similar. They all increase slightly with increasing z then decrease drastically when z is increased beyond 8.0 indicating a structural change. A higher z value may cause an imbalance of the 2:17 ($\text{Th}_2\text{Zr}_{17}$) and 1:5 (CaCu_5) mixture in the cellular structure,⁷ and result in a drastic decrease in H_{ci} , H_c , and H_k when z was over 8.2.

IV. CONCLUSIONS

Structural and magnetic properties of $\text{Sm}(\text{Co}_{0.91-x}\text{Fe}_x\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$, where $x=0, 0.12, 0.21$,

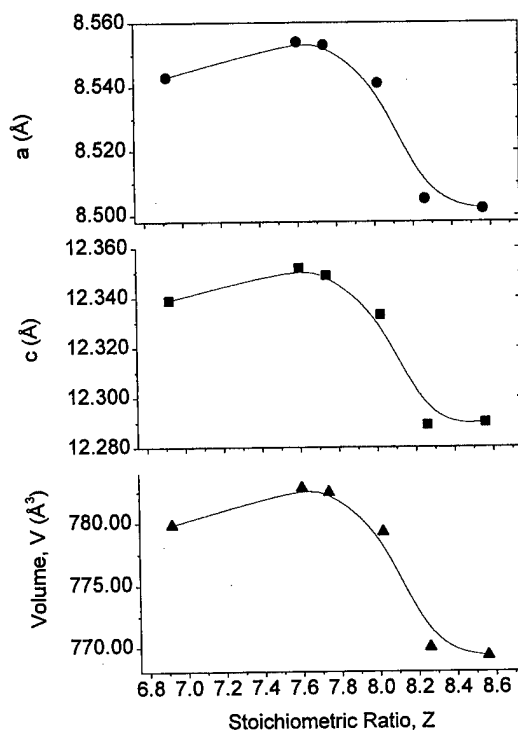

FIG. 5. The variations of lattice parameters a , c and cell volume V of $\text{Sm}(\text{Co}_{0.64}\text{Fe}_{0.28}\text{Cu}_{0.06}\text{Zr}_{0.02})_z$ with z , where z ranges from 6.9 to 8.6.

0.29, and 0.32, and $\text{Sm}(\text{Co}_{0.64}\text{Fe}_{0.28}\text{Cu}_{0.06}\text{Zr}_{0.02})_z$, where z ranged from 6.9 to 8.6, have been systematically investigated. It was found that most of these alloys exhibit a hexagonal $\text{Th}_2\text{Ni}_{17}$ structure with a space group $P6_3/\text{mmc}$ after solid solution treatment. The fully processed materials all exhibit a rhombohedral $\text{Th}_2\text{Zr}_{17}$ structure with a space group of $R\bar{3}m$. For $\text{Sm}(\text{Co}_{0.91-x}\text{Fe}_x\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$, the lattice parameters, a , and c , and cell volume, V , increase slightly with increasing x then increase more sharply when x is increased above 0.28. This drastic increase in lattice parameters and cell volume results in a sharp decrease in H_{ci} , H_c , and H_k values of fully processed materials. For $\text{Sm}(\text{Co}_{0.64}\text{Fe}_{0.28}\text{Cu}_{0.06}\text{Zr}_{0.02})_z$, the lattice parameters, a and c , and cell volume increase slightly when z was varied from 6.8 to 7.8 then decrease drastically when z was increased beyond 8.0. Higher z value may cause an imbalance of the 2:17 and 1:5 mixture in the cellular structure, and result in a drastic decrease in H_{ci} , H_c , and H_k when z was over 8.2.

The effect of particle size on the B_r , BH_{\max} , and specific density of $\text{Sm}(\text{Co}_{0.62}\text{Fe}_{0.29}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ and $\text{Sm}(\text{Co}_{0.70}\text{Fe}_{0.21}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ bonded magnets has been systematically investigated. It was found that magnets made of powders with a top size less than $53\ \mu\text{m}$ have a low specific density and, hence, low B_r and BH_{\max} values. Magnets made of powders of about $250\ \mu\text{m}$ top size, with a composition of $\text{Sm}(\text{Co}_{0.62}\text{Fe}_{0.29}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$, yield a specific density of $7.0\ \text{gm/cc}$ (84% of theoretical density), a B_r of more than $8.1\ \text{kG}$, and a BH_{\max} of about $15\ \text{MGOe}$. A slight decrease in B_r and BH_{\max} was noticed when the particle top size was increased beyond $710\ \mu\text{m}$. This decrease in B_r and BH_{\max} may be attributed to the imperfect grain alignment arising from the fact that each particle may consist of multigrain grains with a random orientation. Because of the slightly lower Fe content, magnets with a composition of $\text{Sm}(\text{Co}_{0.70}\text{Fe}_{0.21}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ exhibit slightly lower B_r and BH_{\max} values when compared to those of $\text{Sm}(\text{Co}_{0.62}\text{Fe}_{0.29}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$. However, the relationships of B_r and BH_{\max} to particle size are nearly identical for both compositions. When the powder top size was fixed at about $250\ \mu\text{m}$, a consolidating pressure of $8\ \text{T/cm}^2$ appears to be sufficient to obtain magnets with a specific density of $6.9\ \text{gm/cc}$ and with a reasonable grain alignment. For $\text{Sm}(\text{Co}_{0.62}\text{Fe}_{0.29}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ bonded magnets, a B_r of $8.5\ \text{kG}$, H_c of $8.5\ \text{kOe}$, H_{ci} of $23.0\ \text{kOe}$, BH_{\max} of $16.7\ \text{MGOe}$, and H_k of $8.0\ \text{kOe}$ were obtained. © 1998 American Institute of Physics. I. INTRODUCTION

$\text{Sm}(\text{Co}, \text{Fe}, \text{Cu}, \text{Zr})_2$ -type bonded magnets have been used commercially for many years.¹ Because of their high operational temperature and potentially high BH_{\max} values, $\text{Sm}(\text{Co}, \text{Fe}, \text{Cu}, \text{Zr})_2$ bonded magnets have generated significant interest for anisotropic applications.²

Anisotropic bonded magnet applications with high BH_{\max} values require the use of powders with high intrinsic BH_{\max} values and/or the optimization of grain alignment and packing density (ρ) during magnet fabrication. In our previous work,³ we have established the effects of particle size and size distribution on the magnetic properties of fully processed $\text{Sm}(\text{Co}, \text{Fe}, \text{Cu}, \text{Zr})_2$ alloy powders. For a given batch of powder, particle alignment and packing density are two interrelated factors that determine the BH_{\max} of bonded magnets. Large particles ($>250\ \mu\text{m}$) are usually multi-grain with random orientation and incapable of being fully aligned. The lower surface to volume ratio of large particles also implies that a high packing density can be obtained without using an excessive amount of binder. Unlike large particles, nearly single crystal grains can readily be obtained on small particles which can result in a nearly perfect grain alignment under an externally applied magnetic field of reasonable strength. However, the increase in surface to volume ratio of powders of small sizes also suggests that a higher percentage of binder may be necessary to achieve reasonable mechanical strength. Moreover, the increase in the volume fraction of

binder will result in a lower packing density and, hence, reduce the B_r and BH_{\max} values of bonded magnets.

The consolidating pressure applied during molding is also an important factor in determining the particle alignment and packing density of bonded magnets. A higher consolidating pressure, for a fixed batch, usually leads to a higher packing density but may cause grain misalignment. Thus, powder particle size and distribution as well as consolidating pressure are important parameters that affect grain alignment and packing density and need to be compromised for obtaining bonded magnets with the highest BH_{\max} .

In this article, we report on the relationships of the magnetic properties obtained on anisotropically bonded $\text{Sm}(\text{Co}, \text{Fe}, \text{Cu}, \text{Zr})_2$ magnets with the particle size distribution and consolidating pressure during molding.

II. EXPERIMENT

$\text{Sm}(\text{Co}_{0.70}\text{Fe}_{0.21}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ and $\text{Sm}(\text{Co}_{0.62}\text{Fe}_{0.29}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ alloys were prepared by conventional vacuum induction melting and mold casting. Alloy ingots were solution treated, precipitation hardened, followed by a slow cooling, and then quenched to optimum conditions. A jaw crusher was utilized to break ingots into millimeter size chunks. Ingot pieces were then fed into a cross-beater mill with various screen sizes to produce powders with various maximum sizes from 53 to $720\ \mu\text{m}$ size sieves. A rotary sieve was used to assure that all powders pass through the predetermined sieve size. A Horiba LA-910 laser particle size analyzer was used to measure the particle size distribution of the powders. Magnets of $10\ \text{mm}$ in diameter and $6.4\ \text{mm}$ in length were

prepared by mixing powders of the desired size with 2 wt% of epoxy, aligned under a 60 kOe magnetic field, and consolidated with a mechanical press under a maximum load of 10 T/cm^2 . To study the effect of consolidating pressure on bonded magnets, the load of the press was controlled from 4 to 10 T/cm^2 .

III. RESULTS AND DISCUSSION

Listed in Table I are the remanence (B_r), coercive force (H_c), intrinsic coercivity (H_{ci}), maximum energy product (BH_{\max}), squareness factor (H_k), and specific density (ρ) of $\text{Sm}(\text{Co}_{0.62}\text{Fe}_{0.29}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ and $\text{Sm}(\text{Co}_{0.70}\text{Fe}_{0.21}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ bonded magnets made from powders of various sizes (from 53 to about $710 \mu\text{m}$ top size) using a consolidating pressure of 10 T/cm^2 . In general, the trends of the two magnet compositions are nearly identical. The variation of ρ , B_r , BH_{\max} , H_c , and H_k of $\text{Sm}(\text{Co}_{0.62}\text{Fe}_{0.29}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ bonded magnets with powder particle sizes are shown in Figs. 1(a)–1(e), respectively. A magnet made from powders of less than $53 \mu\text{m}$ yielded a specific density of 6.40 gm/cc (76% of theoretical density). The ρ increased significantly from 6.40 to 7.00 gm/cc when the powder size was increased from less than 53 to less than $425 \mu\text{m}$ and approached, asymptotically, 7.01 gm/cc (84% of the theoretical density) when the particle size was further increased to nearly $710 \mu\text{m}$. Unlike ρ , the B_r , BH_{\max} , and H_c of $\text{Sm}(\text{Co}_{0.62}\text{Fe}_{0.29}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ magnets all exhibit sharp initial increases, then decrease slightly when the particle top size is increased from 53 to beyond $250 \mu\text{m}$.

Shown in Figs. 2(a) and 2(b) are the optical micrographs of an as-cast and fully processed alloy ingot with a nominal composition of $\text{Sm}(\text{Co}_{0.62}\text{Fe}_{0.29}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$. As can be seen, the as-cast ingot consists of three phases: the matrix phase, a Sm-rich boundary phase and a Zr-rich needlelike phase. The average grain size is about $80 \mu\text{m}$. Significant grain growth can be observed on the fully processed ingot; the average grain size of the fully processed ingot is about $200 \mu\text{m}$. This suggests that powders of small sizes should be

nearly single crystal in each individual particle and, in principle, should yield a better alignment during compaction and result in a high B_r value. Nevertheless, for actual bonded magnets, the B_r is determined by two factors; the grain alignment and the packing density (ρ). The low B_r and BH_{\max} obtained on bonded magnets made from $53 \mu\text{m}$ top size powders suggests that the low ρ was more important than grain alignment. The higher B_r and BH_{\max} values obtained

FIG. 1. Variation of specific density (ρ), B_r , BH_{\max} , H_c , and H_k of $\text{Sm}(\text{Co}_{0.62}\text{Fe}_{0.29}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ bonded magnets with precursor powder particle size.

FIG. 2. Optical micrographs of (a) as-cast and (b) fully processed $\text{Sm}(\text{Co}_{0.62}\text{Fe}_{0.29}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ ingot.

on magnets made from powders of 250 μm top size may be explained by the combination of a reasonable grain alignment and higher ρ obtained. Combining the high ρ and the decreases in B_r and BH_{max} values, one may conclude that imperfect grain alignment (or grain misalignment) may have occurred when the particle size was increased above a 450 μm top size. A similar trend, but less pronounced, was also observed on H_k . Based on these plots, it appears that powders with a top size of 250 μm may yield the highest B_r and BH_{max} values for the magnet fabrication method employed.

TABLE II. The variation of the magnetic properties and specific density of $\text{Sm}(\text{Co}_{0.62}\text{Fe}_{0.29}\text{Cu}_{0.07}\text{Zr}_{0.02})_8$ bonded magnets made from powder of less than 250 μm and with various consolidating pressures.

Sample	Consolidating pressure (T/cm ²)	B_r (kG)	H_c (kOe)	H_{ci} (kOe)	BH_{max} (MGoe)	H_k (kOe)	Specific density (gm/cc)
A	4	7.5	6.7	28.7	12.9	7.2	6.55
B	6	7.7	6.9	28.7	13.6	7.3	6.75
C	8	8.1	7.2	28.8	14.8	7.4	6.88
D	10	8.5	7.4	29.5	16.7	7.8	6.92

FIG. 3. Variation of specific density (ρ), B_r , BH_{max} , H_c , and H_k of $\text{Sm}(\text{Co}_{0.70}\text{Fe}_{0.21}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ bonded magnets with consolidating pressure.

In addition to the particle top size, particle size distribution also plays an important role in determining the impact on ρ , B_r , and BH_{max} of the bonded magnets. The distribution is nearly Gaussian with a mean at 120 μm and a standard deviation of 70 μm . Powders of the other top sizes have a similar distribution as reported elsewhere.⁴

Listed in Table II are the B_r , H_c , H_{ci} , BH_{max} , H_k and ρ of $\text{Sm}(\text{Co}_{0.62}\text{Fe}_{0.29}\text{Cu}_{0.07}\text{Zr}_{0.02})_{8.0}$ magnets made of powders with a particle top size of 250 μm using various consolidating pressures. The variations of ρ , B_r , BH_{max} , H_c , and H_k with consolidating pressure are shown in Fig. 3. A nearly linear relationship between ρ and consolidating pressure can be observed, and shown in the inset of Fig. 3, suggesting that ρ , for the fixed particle size studied, of bonded magnets is a simple function of the consolidating pressure. Using the 250 μm top size powder and the type of binder used in this study, a minimum consolidating pressure of 6 T/cm² is necessary to achieve an 80% theoretical density.

High temperature stability of SmTM magnets

A. S. Kim

YBM Magnex, Inc., 110 Terry Drive, Newtown, Pennsylvania 18940

To meet the demand for permanent magnet materials usable up to 450–500 °C, we investigated and reported that a SmTM magnet with a low temperature coefficient of coercivity and a moderately high coercivity has substantially lower irreversible losses at elevated temperatures than conventional Sm₂TM₁₇ magnets. We have continued our studies on the high temperature magnetic behavior of these magnets. The magnetic properties, particularly coercivity, of the SmTM₇ alloy magnets are reduced much more slowly than the Sm₂TM₁₇ alloy magnets as temperature increases. As a result, the H_{ci} of SmTM₇ remains greater than 5 kOe at 500 °C and thus maintains its high-energy product, while the Sm₂TM₁₇ magnet has only about 1.7 kOe at the same temperature and has a low energy product. SmTM₇ alloy magnets undergoing a long-term stability test at 500 °C exhibit irreversible flux losses of less than 5% after 1240 h. These results indicate that SmTM₇ alloy magnets can be usable up to 500 °C for an extended period of time. This will expand the application temperature range of high performance permanent magnets. © 1998 American Institute of Physics. [S0021-8979(98)41811-5]

I. INTRODUCTION

To fulfill recent requirements for high temperature applications,¹ it is necessary to expand the temperature range of permanent magnet materials from the current maximum operating temperature of 300 °C to 450–500 °C. To meet this demand, we calculated the necessary conditions and designed a magnet satisfying those conditions.²

The operating temperature (OT) of the magnet is expressed as

$$OT = RT + \frac{H_{ci,RT} - H_{ci,OT}}{H_{ci,RT} \times (-\beta)} \times 100\%, \quad (1)$$

where R.T. stands for room temperature, $H_{ci,RT}$ and $H_{ci,OT}$ stand for intrinsic coercivities at room temperature and operating temperature, respectively, and β stands for the temperature coefficient of H_{ci} .

Since the maximum energy product can be obtained when $H_{ci,OT} \geq \frac{1}{2} B_{r,OT}$, it is generally safe to set the minimum $H_{ci,OT} = 5$ kOe at temperature range of 450–500 °C for the maximum operating temperature, as described elsewhere.² Therefore, the Eq. (1) can be rewritten as

$$MOT = RT + \frac{H_{ci,RT} - 5 \text{ kOe}}{H_{ci,RT} \times (-\beta)} \times 100\%. \quad (2)$$

The maximum operating temperature (MOT) is a function of coercivity at room temperature ($H_{ci,RT}$) and the temperature coefficient of coercivity (β). It is noted that the MOT is much more effectively increased by a β decrease than by an $H_{ci,RT}$ increase. This suggests changing our research direction from increasing $H_{ci,RT}$ to lowering the β value while maintaining a moderately high $H_{ci,RT}$ and a high Curie temperature. To develop a magnet meeting such a concept, it is necessary to find out what controls the temperature coefficient of coercivity. Nesbitt *et al.*³ reported that a partial substitution of Cu for Co in SmCo₅ formed a nonmagnetic Cu-rich precipitate in the SmCo₅ matrix, which could impede domain wall motion. Senno *et al.*⁴ reported that the addition

of Cu in Sm₂(Fe,Co)₁₇ exhibited domain wall pinning, and Nagel⁵ reported that Mn and Cr addition in Sm₂(Fe,Co)₁₇ exhibited nucleation controlled magnetization reversal. The former has a much smaller β than the latter. In other words, Cu addition to SmCo₅ or Sm₂(Fe,Co)₁₇ changes the magnetization reversal from nucleation control to domain wall pinning and reduces the β value. With this knowledge, it is possible to predict a further reduction of β by the optimum control of Cu in relation to other elements. Alloy compositions of Sm(Co,Fe,Cu,Zr)_z were varied to find the optimum composition with the lowest β value. We found and reported² that a magnet made from a Cu enriched SmTM₇ alloy possesses a low temperature coefficient of coercivity ($-\beta \leq 15\%/^{\circ}\text{C}$) and moderately high coercivity ($H_{ci,RT} \geq 15$ kOe).

In this study, we will discuss the high temperature magnetic behavior of this magnet compared to a conventional Sm₂TM₁₇ magnet. The possible mechanism for the lower temperature coefficient of coercivity will also be discussed.

II. EXPERIMENT

Two predetermined alloy charges were melted in a vacuum induction-melting furnace. They are

2:17 alloy: Sm(Co_{0.677}Fe_{0.232}Cu_{0.068}Zr_{0.023})₈,

1:7 alloy: Sm(Co_{0.687}Fe_{0.202}Cu_{0.090}Zr_{0.021})₇.

The alloy melts were cast into a copper mold and sintered magnets were prepared from them by a conventional powder metallurgy method described elsewhere.² The magnetic properties were measured at room temperature (21 °C) and at 150 °C with a hysteresigraph and a high temperature search coil. The temperature coefficient of H_{ci} (β) was determined from the magnetic properties measured at 21 and 150 °C. The high temperature magnetic properties were measured up to 600 °C with a VSM equipped with a furnace. The irreversible magnetic flux loss was estimated at a permeance

TABLE I. Magnetic properties at room temperature.

Alloy	B_r , kG	H_{ci} , kOe	H_k , kOe	$(BH)_{max}$, MGOe
2:17	10.16	27.51	9.41	24.71
1:7	8.38	18.68	14.82	17.10

coefficient=1.0 by measuring the flux difference with a Helmholtz coil before and after exposing the magnet to elevated temperatures for 6 h in an argon environment. The microstructure was examined in a transmission electron microscope at the University of Delaware.

III. RESULTS AND DISCUSSION

The magnetic properties at room temperature of the aged magnets are listed in Table I. The magnet made from 2:17 alloy exhibits much higher B_r , H_{ci} , and $(BH)_{max}$ than the magnet made from 1:7 alloy. It is noted, however, that the 1:7 alloy has much better loop squareness (H_k) than the 2:17 alloy. These magnets were measured at 150 °C with the same hysteresisgraph.

The H_{ci} values at 21 and 150 °C, and temperature coefficient of coercivity (β) calculated between 21 and 150 °C are listed in Table II. The 2:17 alloy magnet has $\beta = -0.27\%/^{\circ}\text{C}$, while that of the 1:7 alloy magnet is $-0.14\%/^{\circ}\text{C}$. Since the latter satisfies the necessary conditions described in the Introduction, we examined the thermomagnetic behavior of it at temperatures between 21 and 600 °C by comparing with 2:17 alloy magnets. The coercivities of two 2:17 alloy magnets and one 1:7 alloy magnet measured at 21, 150, 300, 400, 500, and 600 °C are plotted against temperature in Fig. 1. The 2:17 alloy magnets show much higher room temperature coercivities than the 1:7 alloy magnet. However, as temperature increases, the coercivities of 2:17 alloy magnets decrease much faster than that of the 1:7 alloy magnet. This reflects the difference in the temperature coefficient of coercivity. As predicted in the Introduction, the 2:17 alloy magnets reach their maximum operating temperature (MOT) at just above 300 °C ($H_{ci} \geq 5$ kOe), while the 1:7 alloy magnet reaches its MOT at about 500 °C ($H_{ci} \geq 5$ kOe) as shown in Fig. 1.

The magnetic properties measured at 500 °C for both magnets are compared in Fig. 2(a) and Fig. 2(b). The 1:7 alloy magnet exhibits a fairly wide hysteresis loop having a coercivity of 5.1 kOe at 500 °C while the 2:17 alloy magnet exhibits a narrow loop with a low coercivity (~ 1.7 kOe). We also compared the temperature stabilities of these magnets by measuring the irreversible flux losses after exposure to elevated temperatures for 6 h. The irreversible losses of 2:17 and 1:7 alloy magnets are plotted against temperature in

TABLE II. Coercivities at 21 and 150 °C, and temperature coefficient of H_{ci} .

Alloy	H_{ci} , 21 °C, kOe	H_{ci} , 150 °C, kOe	$\beta(21-150\text{ }^{\circ}\text{C})$, %/ $^{\circ}\text{C}$
2:17	27.51	17.80	-0.27
1:7	18.68	15.36	-0.14

FIG. 1. Temperature dependence of coercivity of 2:17 and 1:7 alloy magnets.

Fig. 3. The 2:17 alloy magnet (A) starts to increase irreversible losses at about 300 °C, and the 1:7 alloy magnet (D) at about 500 °C. These temperatures agree well with the MOT values (300 °C for the 2:17 magnet and 500 °C for the 1:7 magnet with $-\beta \leq 0.15\%/^{\circ}\text{C}$) predicted in the Introduction.

The 1:7 alloy magnets undergoing a long term stability test at 500 °C exhibit irreversible flux losses of less than 5% after 1240 h. This indicates that the MOT is dramatically increased by lowering the β value rather than raising the H_{ci}

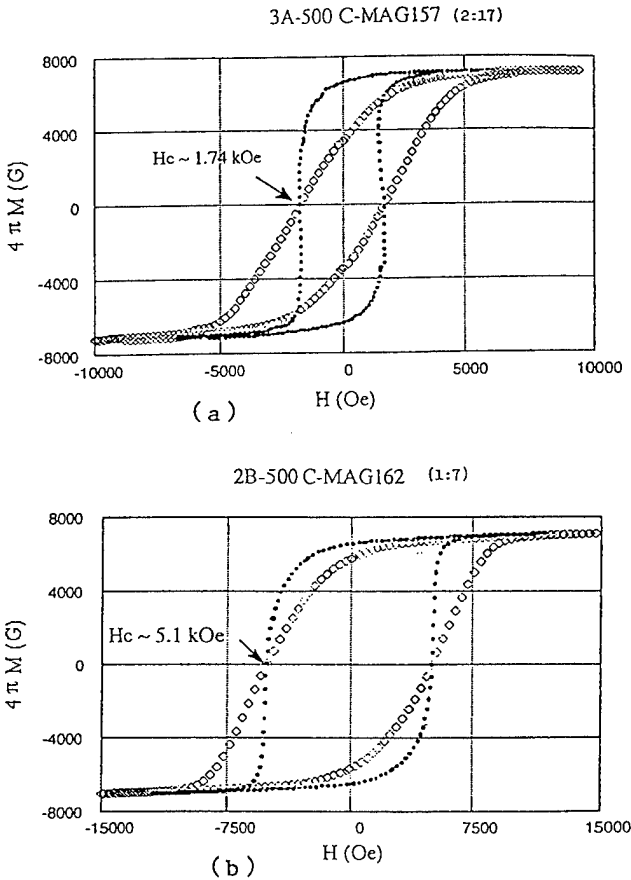

FIG. 2. Hysteresis loops for 2:17 (1) and 1:7 (2) alloy magnets measured with a VSM at 500 °C.

FIG. 3. Irreversible flux losses of magnets A (2:17) and D (1:7) as a function of temperature

value. It is therefore predicted that a further increase in MOT is possible by either further reducing the β value or a combination of lower β and higher H_{ci} values.

To understand the mechanism for the lower temperature coefficient of coercivity of the 1:7 alloy magnet, we compared the microstructures of the 2:17 and 1:7 alloy magnets in a transmission electron microscope. As shown in Figs. 4(a) and 4(d), the 1:7 alloy magnet exhibit a somewhat smaller cell size (2:17 phase) and thicker cell boundaries (1:5 phase) than the 2:17 alloy magnet. The former exhibits a little Z phase, while the latter exhibits much more Z-phase

FIG. 4. TEM micrographs of 2:17 alloy magnet (a) and 1:7 alloy magnet (c).

FIG. 5. Virgin magnetization curves for various sintered SmTM magnets.

precipitation. This microstructural difference may affect the temperature behavior.

We also compared the magnetization curves of these magnets. As shown in Fig. 5, the 2:17 alloy magnet exhibits mixed pinning (strong inhomogeneities), while the 1:7 alloy magnet exhibits homogeneous wall pinning. While a low coercivity 2:17 alloy magnet exhibits weak homogeneous wall pinning,⁶ the 1:7 alloy magnet exhibits much stronger wall pinning. This may originate from the Cu-enriched microstructural change described above and may therefore be responsible for the low temperature coefficient of H_{ci} .

IV. CONCLUSION

We have designed a temperature stable SmTM magnet having a low temperature coefficient of coercivity ($-\beta \leq 0.15\%/^{\circ}\text{C}$) and a moderately high coercivity ($H_{ci} \sim 20$ kOe). A Cu-enriched 1:7 alloy was discovered that effectively reduces the β . High temperature magnetic measurements reveal that the 2:17 alloy magnet can be used up to about 300 $^{\circ}\text{C}$, while the 1:7 alloy magnet whose $-\beta$ is lower than $0.15\%/^{\circ}\text{C}$ can be used up to 500 $^{\circ}\text{C}$. The magnetization curve of the 2:17 alloy magnet exhibits mixed pinning, while that of the 1:7 alloy magnet exhibits strong homogeneous wall pinning. This may be responsible for the low β and for the high temperature stability.

The alloys with composition of $\text{SmCo}_{7-x}\text{Zr}_x$ ($x=0-0.8$) were synthesized and characterized in the temperature range of 10–1273 K and at fields up to 5 T. The experimental results show that a small amount of Zr substitution can contribute to a stabilization of the TbCu_7 structure, and improve magneto-anisotropy H_a from 90 kOe for $x=0$ –180 kOe for $x=0.5$ at room temperature, and from 140 kOe for $x=0$ –300 kOe for $x=0.5$ at 10 K. It is probable that Zr may partly replace a dumbbell of Co atom pair in these alloys. The phase transition between CaCu_5 , TbCu_7 , $\text{Th}_2\text{Zn}_{17}$, and Ce_2Ni_7 at different heat treatment conditions was also discussed. © 1998 American Institute of Physics. I. INTRODUCTION

SmCo_7 is a metastable phase at room temperature with the TbCu_7 structure. The structures of SmCo_7 and $\text{Sm}_2\text{Co}_{17}$ are both derived from the structure of SmCo_5 .^{1,2} The metastable phase SmCo_7 can be obtained by splat cooling,³ meltspinning,² or mechanical alloying.⁴ Some magnetic properties have been reported by Saito *et al.*² They reported that $\text{Sm}_2(\text{Co}, \text{Mn})_{17}$ with the TbCu_7 structure exhibits an anisotropy of 105–140 kOe, which is 1.2–1.4 times larger than that of $\text{Sm}_2(\text{Co}, \text{Mn})_{17}$ with the $\text{Th}_2\text{Zn}_{17}$ structure. In regard to magnet fabrication, it was found that the 1:7 phase plays an important role for developing the cellular structure and the high coercivity in 2:17-type magnets.^{5,6} Interestingly, in 1982, Strnat *et al.* observed that the $\text{Sm}(\text{Co}, \text{Fe}, \text{Cu}, \text{Zr})_{7+x}$ magnets with $x=0$ exhibited less temperature dependence of coercivity than that of magnets with $x>0$.⁷

Currently there is an intense search to find new magnets or to improve existing magnets specifically for high temperature application. A systematic study of the SmCo_7 system will be of use in this regard. In order to stabilize this metastable phase and increase its anisotropy, third element doping is needed. Zr will be the first candidate in this regard, since it was the most effective element for increase of anisotropy in R_2Co_{17} systems.⁹ In the present study, the alloys with a composition of $\text{SmCo}_{7-x}\text{Zr}_x$ ($x=0-0.8$) were synthesized and characterized in the temperature range 10–1273 K and at fields up to 5 T. The structure, magnetic properties, and some phase transformations during heat treatment are reported.

II. EXPERIMENT

Alloys were prepared by arc melting under argon atmosphere. Some of the alloys were then annealed for 72–96 h at various temperatures (600–1100 °C), followed by a water quench. X-ray diffraction (XRD) with Cu radiation, optical microscopy, and scanning electron microscopy (SEM) were used to determine the crystal structure, lattice parameters, and phases present. Magnetic properties (M , H_c , H_a and T_c) were measured in the temperature range of 10–1273 K

and at fields up to 5 T, by using a vibrating sample magnetometer (VSM) and a superconducting quantum interference device (SQUID) magnetometer. The measured samples were in the forms of chunk, loose or aligned powder ($\leq 38 \mu\text{m}$). The anisotropy field (H_a) was determined by measuring the easy and hard axis magnetization on powder aligned in a field of 1.6 T and fixed in a epoxy.

III. RESULTS AND DISCUSSION

A. Structure information of as-cast alloys

Information in regard to the structure and phases present is shown in Figs. 1–3 and Table I.

It was found that the crystal structures of as-cast alloys $\text{SmCo}_{7-x}\text{Zr}_x$ vary significantly with Zr content, x . As shown in Fig. 1, a typical superlattice line for the $\text{Th}_2\text{Zn}_{17}$ structure, 015 and 204, disappears when $x \geq 0.2$. This indicates that the structure of the main phase changes from rhombohedral ($\text{Th}_2\text{Zn}_{17}$ -type) ($x=0$) to hexagonal (TbCu_7 -type) when $x \geq 0.2$. This is also evident from the XRD of aligned samples and a thermomagnetic analysis (TMA). As shown in Fig. 2, the sample with $x=0$ shows two Curie temperatures, $T_{c1} \sim 920$ °C for the 2:17 phase and $T_{c2} \sim 780$ °C for the 1:7

FIG. 1. XRD of $\text{SmCo}_{7-x}\text{Zr}_x$ as-cast alloys ($x=0-0.8$).

FIG. 2. M vs T of $\text{SmCo}_{7-x}\text{Zr}_x$ as-cast alloys ($H=500$ Oe).

phase. For $x=0.2$, it shows one $T_c \sim 760^\circ\text{C}$ for the 1:7 phase (some phase transformations occur above 750°C , which will be discussed later). The sample with $x=0.2$ is nearly a single phase, which was also confirmed by a microstructure examination (SEM). As shown in Fig. 3, its composition was detected to be $\text{Sm} \sim 12.5$, $\text{Co} \sim 85$, $\text{Zr} \sim 2.5$ (at. %) for the main phase (in gray domain), which is very close to $\text{Sm}(\text{Co,Zr}_7)$ and $\text{Sm} \sim 12.7$, $\text{Co} \sim 84.4$, $\text{Zr} \sim 2.9$ (at. %) for the minor phase (in white boundary part). Clearly, Zr stabilizes the hexagonal structure. The lattice parameters c and c/a decrease as x increases. This can be ascribed to a substitution of Zr for Co dumbbells. When the Zr content exceeds 0.4, the XRD intensity of line 101 decreases and some other extra lines, which do not belong to the 1:7 phase, appear. The two T_c is detected by TMA, $T_{c2} \sim (730-750^\circ\text{C})$ for the 1:7 phase and $T_{c3} \sim (430-450^\circ\text{C})$ for the other magnetic phase. Perhaps, this lower T_c phase is an R-rich phase with the hexagonal Ce_2Ni_7 structure or a 1:3 phase. It is to be noted that the above

FIG. 3. Microstructure of $\text{SmCo}_{6.8}\text{Zr}_{0.2}$ as-cast alloy.TABLE I. Phases present and crystal structure of $\text{SmCo}_{7-x}\text{Zr}_x$ as-cast alloys ($x=0-0.8$).

information about the phases present in $\text{SmCo}_{7-x}\text{Zr}_x$ as-cast alloys match nicely with the phase diagram of Derkaui *et al.* of the Sm-Co-Zr system at 1150°C .⁸

B. Magnetic properties of as-cast alloys

The magnetic properties M_s , H_c , H_a , and T_c are given in Figs. 4 and 5. Figure 4 shows the hysteresis loops of loose powder samples with $x=0$, 0.25, and 0.5 at room temperature. The Mr/M and coercivity increase substantially with increase of Zr content. The former may relate to a strengthened interaction between the magnetic particles and the latter should be ascribed to strengthening magnetocrystalline anisotropy fields H_a . As seen in Fig. 5, the H_a increases from 90 kOe ($x=0$) to 160 kOe for $x=0.25$ at room temperature and from 140 kOe ($x=0$) to 230 kOe for $x=0.25$ at 10 K. A decrease of M is reasonable, due to an increase in the amount of nonmagnetic element Zr. The H_c and H_a of the $\text{SmCo}_{7-x}\text{Zr}_x$ compounds increase significantly by an increase of the Zr content. This behavior is very similar to that

FIG. 4. M - H loops of $\text{SmCo}_{7-x}\text{Zr}_x$ as-cast alloys (RT) in loose powder.

FIG. 5. M , H_c , H_a , and T_c vs x (Zr content).

of substitution of Co by Mn or Zr in $\text{Sm}_2(\text{Co}, \text{Mn})_{17}$ ² or $\text{Sm}_2(\text{Co}, \text{Zr})_{17}$ systems.⁹ Deportes *et al.*¹⁰ have pointed out that the Co anisotropy in RCO_5 systems comes primarily from the $2c$ sites. When the Co dumbbells are inserted in place of R, the environment changes in such a way as to reduce the Co anisotropy and also that of the compound. When Zr replaces the dumbbells, the lost anisotropy is restored.

Information about the Curie temperatures of $\text{SmCo}_{7-x}\text{Zr}_x$ (T_c vs Zr content) is given in Fig. 5. As mentioned before, for $x=0$, two T_c , $T_{c1} \sim 920^\circ\text{C}$ for $\text{Sm}_2\text{Co}_{17}$ phase and $T_{c2} \sim 780^\circ\text{C}$ for SmCo_7 phase are observed. As $x > 0$, i.e., Zr doping, the amount of 1:7 phase increases and the 2:17 phase decreases and disappears. The T_{c2} for 1:7 phase slightly decreases with increasing Zr content x from 780°C for $x=0$ to $\sim 730^\circ\text{C}$ for $x=0.5$. The decrease of T_{c2} is not as rapid as that in the case of $\text{Sm}_2(\text{Co}, \text{Zr})_{17}$ system.⁹ For $x \geq 0.4$, another magnetic phase, with $T_{c3} = 430\text{--}450^\circ\text{C}$, was detected. As mentioned before, this lower T_c , but high H_a phase may belong to $(\text{Sm}, \text{Zr})_2(\text{Co}, \text{Zr}_7)$ phase. Further investigations are continuing.

FIG. 6. XRD of aligned powders ($H \sim 1.6$ T) of annealed $\text{SmCo}_{6.8}\text{Zr}_{0.2}$ alloys.FIG. 7. M vs T of annealed $\text{SmCo}_{6.8}\text{Zr}_{0.2}$ alloys.

C. Information about the phase transformation

Figure 6 shows the XRD of aligned powder ($H \sim 1.6$ T) of annealed $\text{SmCo}_{6.8}\text{Zr}_{0.2}$ alloys. Two strengthened lines, 110 and 200, which belong to the 1:7 phase, begin to broaden after annealing above 750°C , and the 1:7 phase begins to decompose. When the annealing temperature increased to 1000°C , two other strengthened lines, 300 and 220, which belong to the 2:17 phase, are clearly showing up and the 2:17 phase precipitates out. The above phase transformation was also observed by TMA measurement as seen in Fig. 7. The T_c for the 1:7 phase varies slightly at different annealing temperatures, which may be associated with a shift in composition. It was found that H_c (loose powder) at room temperature increases from 1.5 kOe for the as-cast sample, to 2.5 kOe when the sample was heated at 800°C followed by a slow cooling to 400°C and decreases to 1.1 kOe after annealing at 1000°C . The increase of H_c may be related to precipitation of a strong anisotropy 2:7 phase, as seen in Fig. 7. The decrease of H_c can be ascribed to the formation of a weak anisotropy 2:17 phase. Similar behavior was also observed in the other alloys ($x=0 \sim 0.5$). Further studies about the effects of heat treatment on magnetic properties are in process.

Coercivity calculation of $\text{Sm}_2(\text{Co,Fe,Cu,Zr})_{17}$ magnets

M. Katter

Vacuumschmelze, Grüner Weg 37, D-63450 Hanau, Germany

The coercivity of $\text{Sm}_2(\text{Co,Fe,Cu,Zr})_{17}$ is calculated on the basis of a two dimensional model. To find local minima of the sum of the domain wall energy and the magnetostatic energy, the domain wall is divided into 1 nm long segments which are allowed to fluctuate randomly. With increasing field strength the domain wall is heavily bowed, forming the well known zig-zag domains. At higher field strengths, the domain wall is depinned first, from the edges of the 2/17 cells and later, from the intersection lines of the Z phase with the 1/5 boundary phase. For these two sites, the widths and the heights of the energy barriers for the movement of the domain walls are calculated in dependence of the applied magnetic field and compared with the thermal activation energy. As a result, the stronger pinning site is stable up to a local field strength of about 40 kA/cm. Since the domain wall generates a demagnetizing field of about 11 kA/cm at the critical position, the coercivity correlated to the stronger pinning site is reduced to 29 kA/cm at room temperature. © 1998 American Institute of Physics. [S0021-8979(98)41911-X]

I. INTRODUCTION

The microstructure of fully heat treated $\text{Sm}_2(\text{Co,Fe,Cu,Zr})_{17}$ magnets consists of rhombohedral $\text{Sm}_2(\text{Co,Fe})_{17}$ (2/17 phase) cells with a diameter of about 100 nm. These cells are surrounded by the Cu-rich cell boundary phase $\text{Sm}(\text{Co,Cu})_5$. Additionally, in magnets with high coercivity there appears a Zr-rich platelet phase (Z-phase) which is precipitated perpendicular to the *c*-axis.^{1,2}

It is well established that the coercivity mechanism of such magnets is of the pinning type. In the past it has been assumed that the domain walls are pinned at the Cu-rich boundary phase.³ In order to explain the fact that magnets with Zr show an about three times larger coercivity than magnets without Zr, a new model for the coercivity mechanism of $\text{Sm}_2(\text{Co,Fe,Cu,Zr})_{17}$ magnets has been proposed recently.⁴ According to this model, the domain walls are pinned at two different pinning sites: in low magnetic fields at the edges of the 2/17 cells and in higher magnetic fields at the intersection lines between the Z phase and the Cu-rich boundary phase. This model was supported by the observation that in $\text{Sm}_2(\text{Co,Fe,Cu,Zr})_{17}$ magnets with high coercivity there exist two distinct demagnetization processes which show different temperature dependences.⁵

So far, this model could only explain that there exist two different pinning sites and that the second one is about 2–3 times stronger than the first one. Assuming plain domain walls, the absolute coercivity was calculated to be only about 1 kA/cm which is more than 10 times smaller than the experimental values.⁶ To overcome this problem, it is the aim of this paper to calculate the coercivity of $\text{Sm}_2(\text{Co,Fe,Cu,Zr})_{17}$ magnets in detail, including the effect of domain wall curvatures and thermal activations.

II. SIMULATION OF DOMAIN WALL MOVEMENT

In a magnetic field, *H*, a domain wall in $\text{Sm}_2(\text{Co,Fe,Cu,Zr})_{17}$ magnets will move and deform to increase the volume fraction where the magnetization is paral-

lel to the applied magnetic field. The final shape and position is determined by local minima of the sum of the magnetostatic energy and the domain wall energy.

For the present calculation, the cellular microstructure of $\text{Sm}_2(\text{Co,Fe,Cu,Zr})_{17}$ magnets is approximated by a two dimensional model, see Figs. 1 and 2.⁴ Following parameters are used: length of the rhombohedral 2/17 cells, *L* = 100 nm; thickness of the 1/5 boundary phase, *d* = 5 nm; inclination angle of the 1/5 phase, $\alpha = 60^\circ$, radius at the edges of the 2/17 cell, *r* = 1 nm; thickness of the Z-phase platelets, *z* = 3 nm; saturation polarization, *J_s*, and domain wall energy, γ , of the phases, $J_{s,2/17} = 1.3$ T, $\gamma_{2/17} = 35$ mJ/m², $J_{s,1/5} = 1.1$ T, $\gamma_{1/5} = 58$ mJ/m², $J_{s,z} = 0.5$ T, $\gamma_z = 11$ mJ/m². The model is set to be periodic parallel to the *c* axis with a periodicity of *L*.

First it is assumed that without applied field, a plain domain wall crosses the 1/5 boundary phase at the edges of the 2/17 cells. For this configuration the magnetostatic energy is zero and the domain wall energy is easily calculated to be $(l_{2/17}\gamma_{2/17} + l_{1/5}\gamma_{1/5} + l_z\gamma_z)1m/L$, where *l*_{2/17}, *l*_{1/5}, and *l_z* are the lengths of the domain wall in the 2/17, 1/5, and Z phase. The factor 1*m/L* is a result of the periodicity of the model. In order to find the local energy minima for an applied magnetic field, the domain wall is divided into short 1 nm long segments which are allowed to fluctuate randomly. After each fluctuation the total energy is calculated by summing up all contributions of the single segments to the domain wall energy and the magnetostatic energy

$$E_{\text{total}} = \sum [l_{2/17}\gamma_{2/17} + l_{1/5}\gamma_{1/5} + l_z\gamma_z - 2H(J_{s,2/17}a_{2/17} + J_{s,1/5}a_{1/5} + J_{s,z}a_z)]1m/L. \quad (1)$$

Here *a*_{2/17}, *a*_{1/5} and *a_z* are the areas of the 2/17, 1/5, and Z phase which have been reversed by the movement of the wall compared to the position at *H* = 0. Due to the two dimensional model, the unit of *E*_{total} is J/m. If this new total energy is lower than the former value then it is taken as

FIG. 1. Shape and position of domain walls in $\text{Sm}_2(\text{Co,Fe,Cu,Zr})_{17}$ magnets for various magnetic field strengths.

starting point for the next iteration. This procedure simulates the effect of the thermal fluctuations in magnets.

For the calculation shown in Fig. 1, wedge-shaped fluctuation volumes were chosen. The length of the wedges were varied randomly between 0 and 10 nm, the width varied from 0 to 2 nm and the position was also determined randomly. The applied magnetic field strength was increased in steps of 0.8 kA/cm and at every new field value, 2000 iterations were tried to find the new equilibrium.

With increasing magnetic field strength the wall bows out in the 2/17 phase quickly and is pressed towards the 1/5 boundary phase. Already at a field strength of about 4 kA/cm, the wall forms the well known zig-zag domains.^{7,8} Additionally, the wall is bowed a little bit in the 1/5 phase too, but it is pinned at the edges of the 2/17 cell. At a field strength of 12 kA/cm, the wall is bowed so strong that it reaches the neighboring 2/17 cell. The wall is depinned and moves up to the next 1/5 boundary. The intermediate positions for 12.8 and 13.6 kA/cm are only a result of the limited number of 2000 iterations per field value. In this state, because of the low domain wall energy of the Z phase, the domain wall preferably follows the Z phase forming domain walls which are almost perpendicular to the c axis. Such wall segments have been recently observed by high resolution Foucault mode Lorentz microscopy.⁸ For field strengths up to 28 kA/cm, the domain wall is still pinned at the intersection line of the Z phase with the 1/5 boundary phase. At this field strength the domain wall is depinned from the second pinning center and the magnet will be completely reversed.

III. ENERGY BARRIERS

In order to be depinned from one of the two pinning sites, the domain wall must overcome an energy barrier. The field dependence of the height and the width of these energy barriers will be calculated below.

FIG. 2. Geometry of the two pinning sites in $\text{Sm}_2(\text{Co,Fe,Cu,Zr})_{17}$ magnets. The domain wall is marked by the thick line.

For the first pinning site at the edges of the 2/17 cell it is assumed, that in the 2/17 cell the domain wall follows the phase boundary to the 1/5 phase, see Fig. 2(a). The section through the 1/5 phase is approximated by an arc segment which intersects the border to the 2/17 phase at an angle β . In the center, the wall deviates by a distance x . For the second pinning site, it is assumed that a straight segment of the domain wall intersects the 1/5 phase at an angle δ , see Fig. 2(b). The width of the cut triangle is y . For the Z phase it is assumed that the domain wall is perpendicular to the c axis.

The total energy is calculated in dependence of the magnetic field strength and the parameters, x and β for the first pinning site, or y and δ for the second pinning site, respectively. The energy is set to zero for the starting positions $x = 0$, $\beta = 0$ or $y = 0$, $\delta = 0$.

Figure 3 shows an example for the second pinning site, calculated for a magnetic field strength of 16 kA/cm. For $\delta = 0$, the total energy initially increases with increasing y and reaches at $y = 3.5$ nm a maximum of about 3.5×10^{-11} J/m. This maximum is a little bit lower for an angle δ of about 20° . So the actual energy barrier for this pinning site has a

FIG. 3. Total energy for the pinning site at the intersection line of the Z phase and the 1/5 boundary phase in dependence of the displacement, y , and the inclination, δ , of the domain wall.

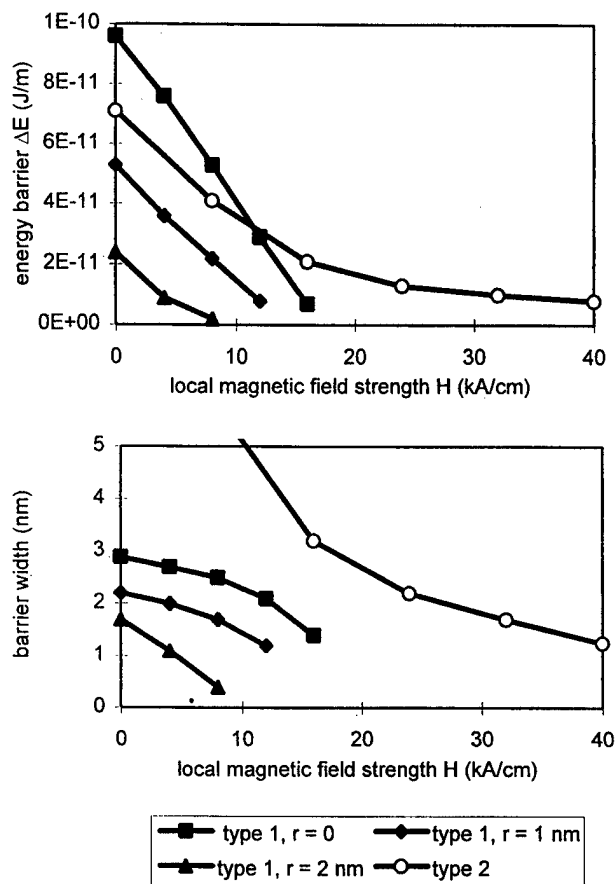

FIG. 4. Field dependence of the width and the height of the energy barriers for various pinning sites in $\text{Sm}_2(\text{Co,Fe,Cu,Zr})_{17}$ magnets.

width of about 3.5 nm and a height of slightly above 2×10^{-11} J/m for an applied magnetic field strength of 16 kA/cm.

Similar calculations were performed for the first pinning site. In this case the width of the energy barrier is determined by the distance between the domain wall and the neighbouring 2/17 cell, Δx , see Fig. 2(a). Hence, the height of the energy barrier is correlated to the total energy at the position where the domain wall reaches the neighbouring cell.

The result of these calculations are shown in Fig. 4. With increasing magnetic field strength both the width and the height of the energy barrier decrease. For the first pinning site, the energy barrier cannot be wider than 3 nm, even for sharp edges. If the edges have a radius of 1 or 2 nm then the width and also the height of the energy barrier is strongly reduced. Depending on this radius, the energy barrier vanishes between about 8 and 17 kA/cm.

The situation is different for the second pinning site. Here the width and the size of the energy barrier decrease slower with increasing magnetic field strength. In particular, at a magnetic field strength of 40 kA/cm, the width of the energy barrier is still 1.2 nm and its height is about 1×10^{-11} J/m.

IV. THERMAL ACTIVATION AND COERCIVITY

The energy necessary to overcome the energy barriers is usually provided by the thermal activation. The thermal activation energy for magnetization states is about $\Delta E_{\text{th}} = 25 \text{ kT}$.⁹ For 300 K this results in $\Delta E_{\text{th}} \approx 1 \times 10^{-19}$ J. This energy is large enough to depinn the domain wall at a length of 10 nm if the energy barrier is 1×10^{-11} J/m. It is assumed that 10 nm is just the length which is necessary to form a stable depinning nucleus. If such a nucleus is once formed then it will expand over the whole length of the pinning site and the domain wall is completely depinned.

Taking 1×10^{-11} J/m as the minimum necessary energy barrier, it turns out that the pinning site at the intersection line of the Z phase and the 1/5 boundary phase is stable up to a local magnetic field strength of 40 kA/cm. The weaker pinning site at the edges of the 2/17 cell is only stable up to 15 kA/cm. If the edges of the 2/17 cell are not sharp, this limit is further reduced, see Fig. 4.

So far the magnetic dipolar interaction has not been taken into account. Therefore, the local magnetic field strengths calculated must be corrected by the demagnetizing field which is generated by the domain wall itself. These demagnetizing fields were calculated by summing up the contributions from each wall segment. Due to the favorable geometry, for the weaker pinning site at the edges of the 2/17 cell the demagnetizing fields almost cancel. Hence the critical fields calculated above are almost identical to the coercivities.

For the stronger pinning site, the demagnetizing field at the critical position is calculated to be about 11 kA/cm. This field strength has to be added to the applied magnetic field. Hence the coercivity of the stronger pinning site in $\text{Sm}_2(\text{Co,Fe,Cu,Zr})_{17}$ magnets is reduced to about 29 kA/cm and determines the coercivity of the magnet.

Finite-temperature behavior of anisotropic two-sublattice magnets

Ralph Skomski

Department of Physics and Astronomy, University of Nebraska, Lincoln, Nebraska 68588-0111

The finite-temperature magnetism of rare-earth transition-metal intermetallics is investigated by extending the n -component vector spin model to two-sublattice magnets. Mean-field analysis shows that the influence of the rare-earth anisotropy on the mean-field Curie temperature is much smaller than expected from the low-temperature rare-earth anisotropy. The use of ultraspherical polynomials yields a generalization of the famous $m(m+1)/2$ power-law exponent to $m(m+n-2)/(n-1)$.

I. INTRODUCTION

Two-sublattice ferro- and ferrimagnets such as $\text{Nd}_2\text{Fe}_{14}\text{B}$, $\text{Dy}_3\text{Fe}_5\text{O}_{12}$, and SmCo_5 are physically interesting and technologically important materials.¹⁻⁴ A particular feature of these materials is that their two-sublattice character is associated with nonequivalent crystallographic sites.⁵⁻⁷ This has to be contrasted to antiferromagnets having equivalent sublattices.^{8,9} For example, the square-lattice Ising antiferromagnet can be mapped onto the square-lattice Ising ferromagnet by simultaneously changing the sign of the exchange and reversing the spins of one sublattice.¹⁰

Rare-earth transition-metal compounds consist of transition-metal and rare-earth sublattices coupled by a comparatively weak intersublattice interaction.^{3,11} For the late iron-series elements the intersublattice exchange between rare-earth and transition-metal spins is antiferromagnetic¹¹ so that, according to Hund's rules, light and heavy rare earths yield ferromagnetic and antiferromagnetic intersublattice coupling, respectively.

Atomic anisotropy energies are small, typically of order $E_a/k_B T \approx 1$ K, but due to interatomic exchange their influence on the magnetic properties is not restricted to low temperatures. Note that the theoretical description of the finite-temperature anisotropy of itinerant electrons is still in its initial stage, whereas the Heisenberg-type magnetism of localized electrons is comparatively well understood. Here we use a generalized n -vector model to investigate anisotropic two-sublattice magnets. Emphasis is put on two questions: (i) the effect the two-sublattice anisotropy on the Curie temperature, and (ii) the finite-temperature behavior of the net anisotropy.

II. MODEL AND CALCULATION

The n -component vector-spin or n -vector model (Fig. 1) is defined in terms of quasiclassical local magnetization vectors obeying $\mathbf{s}^2 = s_1^2 + \dots + s_n^2 = 1$.^{9,12} This definition includes the Ising model ($n=1$, so that $\mathbf{s} = s\mathbf{e}_z$), the planar model ($n=2$, $\mathbf{s} = s_y\mathbf{e}_y + s_z\mathbf{e}_z$), the classical Heisenberg model ($n=3$, $\mathbf{s} = s_x\mathbf{e}_x + s_y\mathbf{e}_y + s_z\mathbf{e}_z$), and the spherical model ($n=\infty$). The $n=0$ model is known as the polymer model.¹³ The n -vector model is widely used to study finite-temperature magnetism.^{9,12} For example, the critical exponents of the spherical model are known exactly.⁹

To generalize the n -vector model we have to introduce separate transition-metal and rare-earth sublattice magnetizations \mathbf{s} and \mathbf{S} , respectively, so that $\mathbf{s}^2 = 1$ and $\mathbf{S}^2 = 1$. The spontaneous sublattice magnetizations are then given by $\mathbf{M}_{sT} = s\mathbf{M}_{0T}$ and $\mathbf{M}_{sR} = S\mathbf{M}_{0R}$, where the index 0 refers to the zero-temperature moment. Let us, for the moment, consider the mean-field Hamiltonian

$$\mathcal{H} = -J_{TT}S_z\langle s_z \rangle - J_{RT}S_z\langle s_z \rangle - J_{TR}S_z\langle S_z \rangle - J_{RR}S_z\langle S_z \rangle - K_T s_z^2 - K_R S_z^2. \quad (1)$$

For the materials of interest, the transition-metal intrasublattice coupling J_{TT} dominates the intersublattice exchange described by J_{RT} and J_{TR} , whereas the rare-earth intrasublattice exchange J_{RR} is negligibly small. K_T and K_R are the lowest-order uniaxial transition-metal and rare-earth sublattice anisotropy constants, respectively, and refer to the magnetic energy per atom. Due to the pronounced rare-earth spin-orbit coupling, $K_R \gg K_T$ for typical magnets. An exception are rare earths whose $4f$ electron cloud is spherical, such as gadolinium. Note that putting $J_{RT} = J_{TR} = K_R = 0$ and $K_T = K_R = 0$ yields, for $n=3$, the well-investigated limits of the anisotropic one-sublattice¹⁴ and isotropic two-sublattice^{6,7} Heisenberg models, respectively.

The equilibrium behavior of the model Eq. (1) is given by the partition function

$$Z = \int' \exp(-\mathcal{H}/k_B T) d\mathbf{s} d\mathbf{S}. \quad (2)$$

Here, the dash indicates that the conditions $\mathbf{s}^2 = 1$ and $\mathbf{S}^2 = 1$ restrict the integration to the surfaces of n -dimensional spheres. The thermally averaged sublattice magnetizations

FIG. 1. Spin configurations: (a) $J=5/2$ Heisenberg model, (b) Ising model, (c) planar model, and (d) classical Heisenberg model.

FIG. 2. Temperature dependence of magnetocrystalline anisotropy if both K_T and K_R are positive (schematic).

$M_{sT}\langle s_z \rangle$ and $M_{sR}\langle S_z \rangle$ and anisotropies $K_T\langle s_z^2 \rangle$ and $K_R\langle S_z^2 \rangle$ are obtained by direct integration or, more conveniently, by differentiating Eq. (2) with respect to $\langle s_z \rangle$ and $\langle S_z \rangle$. The resulting self-consistent equations are, in general, coupled and nonlinear. Mathematically, the calculation involves surface averages such as $\langle z^m \rangle_0 = \int' z^m d\mathbf{x} / \int d\mathbf{x}$. In particular, $\langle z^2 \rangle_0 = 1/n$ and $\langle z^4 \rangle_0 = 3/n(n+2)$.

A. Curie temperature

In the vicinity of the Curie temperature it is possible to expand Z into powers of the small quantities $\langle s_z \rangle$ and $\langle S_z \rangle$. As in the case of isotropic two-sublattice magnets,^{6,7} the determination of the Curie temperature reduces to the calculation and diagonalization of a 2×2 secular matrix equation. In the present case,

$$\begin{pmatrix} \langle s_z \rangle \\ \langle S_z \rangle \end{pmatrix} = \begin{pmatrix} A_{TT} & A_{TR} \\ A_{RT} & A_{RR} \end{pmatrix} \begin{pmatrix} \langle s_z \rangle \\ \langle S_z \rangle \end{pmatrix}, \quad (3)$$

where

$$A_{ik} = (J_{ik}/nk_B T) \{1 + [2(n-1)K_i]/[n(n+2)k_B T]\}. \quad (4)$$

Neglecting J_{RR} and taking into account the smallness of J_{RT} , K_T , and K_R , we obtain by eigenvalue analysis

$$T_c = T_T + T_{RT}^2/T_T + \{2(n-1)/[n(n+2)k_B]\} (K_T + K_R T_{RT}^2/T_T^2), \quad (5)$$

where $T_T = J_{TT}/nk_B$ and $T_{RT} = \sqrt{J_{RT}J_{TR}/n^2 k_B^2}$.

The first two terms on the right-hand side of Eq. (5) are well known and describe the isotropic transition-metal and rare-earth contributions to the Curie temperature, respectively.^{3,7} The third term on the right-hand side of Eq. (5) is the anisotropy contribution to T_c . We see that the influence of the rare-earth anisotropy is smaller than expected from the value of K_R by a factor T_{RT}^2/T_T^2 , that is of order 0.05 for iron-rich rare-earth intermetallics.

Note that the anisotropy of the ideally anisotropic Ising model ($n=1$) does not contribute to the Curie temperature, but from the leading term $T_T = J_{TT}/nk_B$ we see that the Ising Curie temperature is about three times larger than the Heisenberg Curie temperature.

B. Anisotropy

Figure 2 gives a schematic idea of the temperature dependence of the total anisotropy. Here we neglect the low-temperature and critical limits (dashed lines) and focus on the intermediate regimes $T < T_{RT}$ and $T_{RT} < T < T_c$. In the classical Heisenberg model, the temperature dependence of m th-order anisotropy contributions is proportional to the thermal average of the Legendre polynomials $\langle P_m(S_z) \rangle_0$, where the index 0 refers to the isotropic Hamiltonian.¹⁴ For the n -vector model we have to use ultraspherical polynomials $P_m^{(n)}(x)$.¹⁵ The first ultraspherical polynomials are $P_{0(n)} = 1$, $P_{1(n)} = x$,

$$P_{2(n)} = \frac{1}{n-1} (nx^2 - 1), \quad (6a)$$

$$P_{3(n)} = \frac{1}{n-1} [(n+2)x^3 - 3x], \quad (6b)$$

and

$$P_{4(n)} = \frac{1}{n^2-1} [(n+2)(n+4)x^4 - 6(n+2)x^2 - 1]. \quad (6c)$$

For $n=2$, the ultraspherical polynomials are also known as Tchebicheff polynomials.

At low temperatures, the magnetization dependence of the Heisenberg anisotropy constants $K_{m/2}$ is given by the famous power-law $K(T)/K(0) = (M_s/M_0)^{m(m+1)/2}$ (Ref. 14). For example, $K_1(T)/K_1(0) = (M_s/M_0)^3$. Let us now generalize this power law to arbitrary spin dimensionalities, which is of some interest because statistical considerations often simplify in the limit of large spin dimensionalities. The starting point is the "low-temperature" expression $\int' \exp(z/t) z^m d\mathbf{x} = 1 - m(n-1)t/2$. By expressing the ultraspherical polynomials in terms of hypergeometric functions,¹⁵ we find after short calculation

$$K_1(T)/K_1(0) = (M_s/M_0)^{m(m+n-2)/(n-1)}. \quad (7)$$

Note that the exponent in this equation equals m in the spherical model and $2n/(n-1)$ for the lowest-order anisotropy constant ($m=2$).

Equation (7) is restricted to one-sublattice magnets, but at very low temperatures $T < T_{RT}$ it remains valid if M_s and M_0 refer to the rare-earth sublattice magnetization. In the practically important intermediate region $T_{RT} < T < T_c$, one has to consider the rare-earth sublattice in the exchange field of the transition-metal sublattice,^{3,17} which yields the approximate $1/T^4$ power-law

$$\frac{K_R(T)}{K_R(0)} = \frac{J_{RT}^2}{n(n+2)k_B^2 T^2}. \quad (8)$$

This prediction agrees fairly well with numerical studies on a quantum-mechanical single-ion model¹⁶ and the estimate $A = 1.7 \pm 0.4$ deduced from literature data on $\text{Sm}_2\text{Fe}_{17}\text{N}_x$ and $\text{Sm}_2\text{Fe}_{17}\text{C}_x$.⁴

C. Transition-metal sublattice

The itinerant character of the 3d electrons means that not only the spontaneous magnetization but also the mag-

netic moment are temperature dependent.¹⁷⁻¹⁹ However, in most cases the thermal reduction of the magnetic moment does not exceed a few percent so that its neglect is a fair assumption.¹⁷⁻¹⁹ As a very crude approximation, we consider the mean-field Hamiltonian

$$\mathcal{H} = -J_{TT}s_z\langle s_z \rangle - K_T s_z^2 - U_0 s^2, \quad (9)$$

where $n=3$ and $s^2 \leq 1$ and the parameter $U_0 \propto I - 1/D(E_F)$ is a Stoner-type single-site energy.¹⁹ Typically, $U_0 \gg J \gg K_T$, so that in lowest-order $T_c = T_T(1 + 4K_T/15k_B T_T - 2T_T/U_0)$. The reduction of T_c is small in the region where Eq. (9) applies, but may nevertheless be larger than the K_1 contributions discussed in this paper.

In lowest order, the transition-metal anisotropy is given by the linear relation¹⁴

$$K(T) = K(0)(1 - T/T_c). \quad (10)$$

Note that this temperature dependence is even simpler than that of the spontaneous magnetization, which exhibits an implicit dependence on the Langevin function.

III. DISCUSSION AND CONCLUSIONS

The ultimate reason for the weak K_R dependence in Eq. (5) is that the two sublattices are largely decoupled above T_{RT} . In the vicinity of T_c , the sublattice magnetizations are given by the eigenmode

$$\langle m_z \rangle = \langle s_z \rangle + \frac{T_{RT}}{T_c} \langle S_z \rangle, \quad (11)$$

showing that the mean-field magnetization near T_c is dominated by the transition-metal sublattice. Of course, the mean-field approximation is incorrect in the vicinity of T_c .¹⁰ However, the thermal sublattice decoupling is a mean-field effect starting far below T_c and being most pronounced at high temperatures. As a consequence, even for $K_T=0$ the rare-earth critical behavior is difficult to observe.

The key advantage of the n -vector model, namely its transparent physical meaning, is paid by an incorrect description of quantum-mechanical spin excitations. In particular, the classical n -vector model neglects the nonzero energy spacing between the quantum levels [Fig. 1(a)] and does not work very well at low temperatures (the "plateau" region in Fig. 2).¹⁶ Furthermore, Eq. (1) neglects exchange

anisotropy²⁰ and magnetostatic dipole interactions. For this reason, our predictions are only semiquantitative.

In conclusion, we have analyzed the finite-temperature behavior of a generalized n -vector model. The influence of transition-metal and rare-earth anisotropies on the Curie temperature is treated in a mean-field approximation. Due to the weakness of the intersublattice coupling, the anisotropy contribution to the Curie temperature is determined by the transition-metal sublattice. The temperature dependence of the anisotropy may be approximated by a hierarchy of power laws.

The easy magnetization direction of DyCo₁₀V₂ is parallel to the *c* axis at room temperature. The magnetization hysteresis loops of magnetically aligned samples were measured from 5 to 300 K with fields applied parallel and perpendicular to the alignment direction. For samples field-cooled to below the compensation temperatures, shifts of the loop centers into the range of negative magnetizations were observed. These features and the occurrence of negative remanences are explained in terms of the magnetization reversal when passing the compensation temperature upon cooling. From measurements of the temperature dependence of the magnetization, it was derived that a spin-reorientation transition takes place at about $T_{SR} = 41$ K. © 1998 American Institute of Physics. [S0021-8979(98)35411-0]

I. INTRODUCTION

The RCo₁₀V₂ compounds have the tetragonal ThMn₁₂ structure and it was shown by neutron diffraction that the V atoms occupy almost exclusively the 8*i* site, leaving only small occupancies for the 8*f* and 8*j* sites.¹ Magnetic measurements have shown that the Curie temperatures are well above 400 K and that the atomic Co moments in these compounds are about 0.8 μ_B .² The Co-sublattice anisotropy favors an easy magnetization direction perpendicular to the *c* axis.³ Depending on the nature of the rare-earth component and the concomitant second order Stevens factor, the rare-earth sublattice anisotropy may favor an easy magnetization direction parallel to the *c* axis at low temperatures and lead to a spin-reorientation transition in the low-temperature range. Such behavior is expected for the compound DyCo₁₀V₂. In addition, due to the ferrimagnetic coupling between the Dy and Co moments, the magnetization reversal process is expected to be different in the temperature ranges above and below the compensation temperature. For this reason, we have studied the magnetic properties of this compound in more detail, including hysteresis loops at different temperatures.

II. EXPERIMENT

The DyCo₁₀V₂ compound was prepared by melting stoichiometric proportions of the constituent metals (purity at least 99%) in an argon-arc furnace. Subsequently, the sample was wrapped in Ta foil and annealed for three weeks at 1050 °C in an evacuated quartz tube. After annealing, the sample was investigated by x-ray diffraction. Inspection of the x-ray diagram showed that a single-phase compound of the ThMn₁₂-type structure had formed.

The field and temperature dependences of the magnetization of the DyCo₁₀V₂ compound were studied by means of a SQUID magnetometer. The magnetic isotherms were measured on magnetically aligned powders with the measuring fields applied parallel and perpendicular to the alignment direction.

III. RESULTS AND DISCUSSION

From x-ray diffraction made on a magnetically aligned powder sample of the DyCo₁₀V₂ compound, it is derived that the easy magnetization direction is parallel to the *c* axis. The x-ray diagram of the aligned sample can be compared in Fig. 1 with the diagram measured on a powder sample in which the particles are oriented at random.

Measurements of the temperature dependence of the magnetization were made in various fields with increasing temperature on a piece of bulk material containing a statistical distribution of grain orientations. Results are shown in Fig. 2. The measurements were made after cooling the sample to 5 K in zero field. The minimum in the upper two curves at about 120 K corresponds to the compensation temperature (T_{comp}). Below this temperature, the magnetization is Dy dominated and above this temperature Co dominated. This means that the total magnetization, in order to become oriented parallel to the field direction, has to revert its direction when passing through T_{comp} . Alternatively, one could say that the applied field is parallel to the total magnetization below T_{comp} and antiparallel to it above T_{comp} . Because of the presence of a large coercivity, the total magnetization is not able to revert its direction when the measuring fields are too small. This is the case for the lower three curves shown

FIG. 1. X-ray diagrams of (a) an unaligned sample, and (b) a magnetically aligned sample of DyCo₁₀V₂.

FIG. 2. Temperature dependence of the magnetization of a piece of bulk material of $\text{DyCo}_{10}\text{V}_2$, fixed with epoxy, measured in various applied fields with increasing temperature from 5 K to room temperature.

in Fig. 2. We will show below that the coercivity strongly decreases with increasing temperature. This means that the higher the applied field, the sooner will the total magnetization be able to revert its direction above T_{comp} . This may explain why the sample, when measured with comparatively low fields, retains its original magnetization with negative values even up to room temperature for $B = 0.001$ T.

It can be seen in Fig. 2 that all the curves show a discontinuity at about 41 K. This discontinuity is attributed to a spin reorientation. The Co-sublattice anisotropy favors an easy magnetization direction perpendicular to the c axis.³ We have shown above that the easy magnetization direction in the $\text{DyCo}_{10}\text{V}_2$ compound is parallel to the c axis at room temperature. This means that the Dy-sublattice anisotropy, which depends much stronger on temperature than the Co-sublattice anisotropy, has been able to overcompensate the Co-sublattice anisotropy already at room temperature. This excludes the possibility for a type of spin reorientation that might originate from a competition between these two sublattices below room temperature. Because the Dy-sublattice anisotropy is crystal-field induced, anisotropy contributions due to higher order crystal-field terms gain in importance upon decreasing temperature and may be responsible for the spin reorientation at $T_{\text{SR}} \approx 41$ K. This spin reorientation may lead to an easy-cone configuration, allowing for a small component of the magnetization perpendicular to the c axis. Because the anisotropy within the basal plane is commonly only very small, this cone configuration leads to a small enhancement of the magnetization for statistically oriented grains below T_{SR} . A similar type of spin reorientation transition has been observed at cryogenic temperatures, for instance, in the compound $\text{Nd}_2\text{Fe}_{14}\text{B}$.

It is well known that the coercivity depends strongly on the magnetic anisotropy. The anisotropy field can be expressed in terms of the anisotropy constant K_1 (neglecting higher-order terms for the sake of simplicity) and the saturation magnetization M_s via the relation $H_A(T) = 2K_1(T)/\mu_0 M_s(T)$. This means that the anisotropy field of the $\text{DyCo}_{10}\text{V}_2$ compound will be particularly strong in the

FIG. 3. Coercive behavior of $\text{DyCo}_{10}\text{V}_2$ particles, magnetically aligned and fixed at room temperature (a) when measured at room temperature, when measured after cooling in 5 T to the measuring temperature of (b) 70 K, (c) 5 K. Coercive behavior of particles magnetically aligned parallel to the c direction, fixed with epoxy, and measured with the applied field parallel to the alignment direction after cooling in zero field, (d) first to 70 K, (e) then to 5 K.

low-temperature region, not only because K_1 increases strongly with decreasing temperature but also because of the mutual compensation of the magnetization of the two sublattices. The room-temperature hysteresis loops for magnetically aligned powder particles are shown in Fig. 3(a). The mutually antiparallel Dy and Co sublattice moments can bend towards each other in the applied field when the latter is perpendicular to the alignment direction. For this reason, the net moment can become higher in comparatively high fields than when measurements are made with the field applied parallel to the alignment direction. This may explain the crossing of the two isotherms shown in Fig. 3(a).

Measurements of the hysteresis loops at 70 and 5 K are shown in Figs. 3(b) and 3(c), respectively. These were obtained by applying a field of 5 T in the alignment direction and, subsequently, cooling the sample to 5 K and/or 70 K in the same field. It can be derived from the shape of the loops measured at 5 and 70 K that these are minor hysteresis loops. When interpreting the results shown in Figs. 3(b) and 3(c) one has to bear in mind that the applied field is much higher than the coercivity at high temperatures. This means that the domain walls are removed from the particles by the applied field and that the magnetization of the particles corresponds

to a location on the upper branch of a hysteresis loop. This situation is basically retained when cooling the sample to lower temperatures in the presence of the same field. However, because the compensation temperature is passed when cooling down, the magnetization has changed its direction. The applied field is now opposite to the magnetization direction. This is the reason why the loops measured in parallel direction have their center at negative values of the magnetization. Furthermore, the fact that the remanence is still negative makes it clear that fields substantially higher than 5 T would be required for reaching complete magnetization reversal and for reaching the maximum coercivity. In fact, for perfectly aligned particles one would have expected a magnetization behavior corresponding to the quasilinear behavior when traversing the lower branch rather than upper branch of an extremely wide hysteresis loop. However, superimposed on this quasilinear behavior is probably the loop behavior of less well aligned particles. Computer simulations and model calculations^{4,5} have shown that the coercivity can become strongly reduced when the particle alignment deviates from the parallel direction. This is very likely also the reason for the comparatively small coercivities found in the loops in Figs. 3(b) and 3(c) measured with the field perpendicular to the alignment direction. Note that the magnetization reversal associated with T_{comp} should not have any influence when the measurements are made perpendicular to the magnetization direction, but the less ideal alignment already mentioned may shift the centers of these loops somewhat into the region of negative magnetizations.

The results displayed in Figs. 3(d) and 3(e) describe experiments made on samples aligned parallel to the c axis and cooled to 70 and 5 K in zero field. At room temperature the

sample can be regarded as demagnetized, a situation that will not have changed much by the small field of 0.04 T used for positioning the sample in the magnetometer. The demagnetized state is retained when cooling to 5 and 70 K. Because we expect the maximum coercivity to be higher than 5 T, the hysteresis loops measured up to the latter field have to be regarded as minor loops, which obviously is the case.

Finally, we wish to comment on the wasp-tailed shape of the various loops shown in Fig. 3. This shape suggests the presence of particles having different coercivities. We mentioned already the influence of particle misalignment on the loop behavior. However, one has also to take into consideration that the particle size is not uniform, and that the samples may contain very small particles with single-domain character and high coercivities as well as a whole gamut of larger sized particles with multidomain character and lower coercivities.

Marked changes of the main structural and magnetic properties of the RFe_{11}Ti phases are induced by hydrogen insertion. High field magnetization measurements are reported on magnetically oriented $\text{ErFe}_{11}\text{Ti}$ and $\text{ErFe}_{11}\text{TiH}$ samples under a field up to 240 kOe (24 T) in the 4.2–300 K temperature range. A raise of the Curie temperature and room temperature saturation magnetization upon hydrogen insertion is observed. The $M(H)$ curves show a significant susceptibility is observed even at room temperature. The magnetic anisotropy constants are determined. Isofield magnetization curves reveal broad maxima in the 230 K range which reflect the fast decrease of the Er sublattice under high field. © 1998 American Institute of Physics. I. INTRODUCTION

The seek for permanent magnet materials has led to the discovery of compounds of the type $\text{RFe}_{12-x}\text{M}$ (R=rare earth or yttrium and M=transition metal element). These intermetallic compounds stabilize with the ThMn_{12} structure type whose space group is $I4/mmm$. For selected R or M, potentially hard magnetic materials are obtained among which one can cite $\text{SmFe}_{11}\text{Ti}^{1-3}$ and $\text{SmFe}_{11}\text{TiH}^{4,5}$ where insertion of hydrogen induces an enhancement of the magnetic features. RFe_{11}Ti phases have also attracted much attention for fundamental research. Many of these RFe_{11}Ti compounds are exhibiting spin reorientation (SR) at low temperatures.^{3,6,7} Till now the $\text{RFe}_{11}\text{TiH}$ phases have been less studied, here we focus on the magnetic properties of $\text{ErFe}_{11}\text{Ti}$ and $\text{ErFe}_{11}\text{TiH}$.

The sample preparation and sample analysis have been described in Ref. 4. The amount of absorbed hydrogen estimated by the gravimetric, as well as the volumetric method was one H atom per $\text{ErFe}_{11}\text{Ti}$ formula unit. This content has been confirmed by neutron diffraction. Thermomagnetic analysis was performed using a home-made Faraday type balance by recording magnetization (M) versus temperature (T). High field magnetization measurements have been performed on both $\text{ErFe}_{11}\text{Ti}$ and $\text{ErFe}_{11}\text{TiH}$ in a continuous magnetic field up to 240 kOe. Magnetic measurements over the temperature range 4.2–300 K were performed using an automatic system provided with a cryostat associated with a calorimeter and described in Ref. 8. The experimental accuracy on M is estimated to be $\pm 2\%$.

No single crystals of the hydrogen containing compound were available, thus, in order to work in the same conditions, both compounds have been studied on a polycrystalline sample. The samples were made from oriented powders with a particle size smaller than 25 μm . The magnetic field was applied either parallel or perpendicular to the alignment direction. The powder was aligned at room temperature using

an orientation field of typically 10 kOe and fixed in epoxy resin. Magnetization isofield curves have been measured between 50 and 300 K in order to obtain the thermal variation of the magnetization. The saturation magnetization has been obtained from extrapolation of the $M(H)$ curve with H parallel to the alignment direction according to $M(H) = M_{\text{sat}} + a/H^2$. The magnetocrystalline anisotropy of uniaxial crystals is given by $K_1 \sin^2 \theta + K_2 \sin^4 \theta$, where θ is the angle between the easy direction of magnetization and the magnetization (anisotropy constants of higher order than K_2 being neglected). The anisotropy constants K_j has been deduced from the fitting of the magnetization curves: Refs. 9 and 10. This approach was successfully used to determine the constants for the $\text{SmFe}_{11}\text{Ti}$ compound,⁴ leading to values equivalent to that obtained from single crystals.¹¹ The analysis of the x-ray diffraction pattern shows that the $I4/mmm$ symmetry is kept after hydrogen insertion. The lattice parameters of the hydride are larger than that of the host alloy. This is a rather common features in the rare-earth-iron intermetallics. The estimated H uptake (1 atom per formula unit) is in good agreement with the localization of hydrogen deduced from neutron diffraction experiments.^{12,13} In $\text{ErFe}_{11}\text{TiH}$, hydrogen atoms are found to be exclusively located in the octahedral $2b$ site. In this site, H atoms are surrounded by two erbium atoms and four iron atoms.

II. RESULTS AND DISCUSSION

The ordering temperatures are 518 and 574 K for $\text{ErFe}_{11}\text{Ti}$ and $\text{ErFe}_{11}\text{TiH}$, respectively. This is clearly evidenced in an enhancement of the exchange interaction and has to be related to the unit cell increase mentioned above. According to the Néel–Slater curve, in the range of interatomic distances observed in RFe_{11}Ti compounds, an increase of the Fe–Fe interatomic distance produces an enhancement of the Fe–Fe exchange interaction. According to x-ray diffractometry performed on magnetically aligned powder, both $\text{ErFe}_{11}\text{Ti}$ and $\text{ErFe}_{11}\text{TiH}$ compounds exhibit an uniaxial easy magnetization at room temperature. This is not

FIG. 1. Isothermal magnetization curves at 300 K on oriented ErFe₁₁Ti up to 240 kOe.

that surprising since previous investigations on RFe₁₁Ti alloys and hydrides R=Y, Lu, and Gd^{4,5,13} have shown that, in this structure, the iron sublattice anisotropy favors an alignment of the magnetic moment along the *c* axis and that for rare earth elements having a positive second order Stevens coefficient, α_J (Sm,Er,Tm), the easy axis is also the *c* axis.

Nevertheless, a spin reorientation (SR) phenomenon has been observed for cooling below room temperature.^{1,3,14} Neither Tm, nor Sm containing compounds are exhibiting such a SR, it was thus suggested that in the RFe₁₁Ti structure the first order crystal electric field parameter A_0^2 is not sufficient to understand the low temperature magnetic features, higher order parameters have to be taken into account, in particular with different behaviors of comparison with Sm and Tm, one may arise from the highest value of the γ_J Stevens coefficient in the case of erbium.¹⁵

This evidenced in the RFe₁₁Ti families of compounds that higher than two order crystal electric field parameters have to be taken into consideration to understand the contribution of the rare earth sublattice to the magnetocrystalline anisotropy. This conclusion was also drawn from the analysis of RFe₁₁Ti compounds (i.e., Dy).^{6,15} The magnetization curves recorded at room temperature on oriented powder are given in Figs. 1 and 2 for ErFe₁₁Ti and ErFe₁₁TiH, respectively. Unlike what was measured for other rare earth elements, a significant susceptibility is observed for the ErFe₁₁Ti and ErFe₁₁TiH even at room temperature and a rather high magnetic field. This feature was not pointed out by Andreev *et al.*¹⁴ but is also present on their single crystal data. The main magnetic features deduced from these curves are summarized in Table I. The purity of the sample is confirmed by the magnetization obtained from our sample which is very close to the ErFe₁₁Ti single crystal data.¹⁴ M_{sat} is found to be slightly higher for the alloy 15.7 μ_B / formula unit against 15.0 for the hydride. Since the iron sublattice magnetization is almost insensitive to the presence of

FIG. 2. Isothermal magnetization curves at 300 K on oriented ErFe₁₁TiH up to 240 kOe.

hydrogen,^{4,5,13} the observed decrease of the overall magnetization induced by hydrogen insertion reflects an increase of the Er sublattice magnetization at room temperature.

The anisotropy constants K_1 and K_2 are in agreement with an alignment of the total magnetization along the *c* axis. A slight decrease of the parameter K_1 is found after hydrogenation. The low temperature magnetization curves (4.2 K) are plotted in Fig. 3. M_{sat} is found to be 11.6 μ_B / formula for ErFe₁₁Ti; this value agrees with that obtained on a single crystal.¹⁴ If one subtracts the Fe sublattice magnetization (about 17 μ_B / formula) deduced from the study on LuFe₁₁Ti or YFe₁₁Ti,¹² about 5.4 μ_B is obtained for Er. Note that this value reflects the projection of the Er magnetization along the *c* axis. It is worth noting that since the Er atoms are located on a fourfold axis (position 2*a* of space group I4/mmm) one may expect four equivalent directions of the Er magnetic moment each tilted on a angle θ with respect to the *c* axis and a pyramidal arrangement seems more probable than that of a simple cone as usually proposed. A continuous rotation (decrease of the angle θ) has been observed on a ErFe₁₁Ti single crystal when the temperature increases.¹⁴ The same thing may be expected for the corresponding hydride, nevertheless the θ angle can be different from that

TABLE I. Magnetic features of ErFe₁₁Ti and ErFe₁₁TiH.

FIG. 3. Isothermal magnetization curves at 4.2 K on oriented $\text{ErFe}_{11}\text{Ti}$ up to 240 kOe.

observed for the alloy since hydrogen insertion modifies the crystal field parameters at the rare earth site.¹⁶

The magnetization curve recorded for $\text{ErFe}_{11}\text{Ti}$ at 4.2 K evidences a peculiar behavior at about 70 kOe where a change of the slope is observed on the curve measured when applying the field perpendicularly to the alignment direction. Since such peculiar behavior is not observed at high temperatures, we suggest that from 70 kOe all the magnetic moments are titled in respect to the c axis, whereas at higher magnetic fields the magnetization is along the c axis (the θ angle has vanished). Following this interpretation, the anisotropy constant have been extracted from the magnetization curve obtained at field between 70 and 240 kOe (Table I).

The isofield magnetization curves given in Fig. 4 are characterized by a broad maximum which decreases when the applied field increases; this maximum is found at 248 and 228 K for $\text{ErFe}_{11}\text{Ti}$ at 10 and 230 kOe, respectively. In $\text{ErFe}_{11}\text{TiH}$, the maximum is observed at slightly higher temperatures, typically 265 and 236 K on an applied field of 10 and 230 kOe, respectively. Whatever the magnetic field, a sharp raise of the magnetization is observed as the temperature increases towards the maximum. This reflects the fast decrease of the Er magnetic moment versus temperature while the Fe sublattice remains almost constant in this temperature range. After this broad maximum of the magnetization, the total magnetization decreases due to the decrease of the Fe sublattice magnetization.

Hydrogen insertion in $\text{ErFe}_{11}\text{Ti}$ does not modify the magnitude of the Fe sublattice magnetization much as discussed elsewhere.^{4,12,5} The displacement of the maximum towards the higher temperature indicates an enhancement of the Er magnetization upon H insertion in $\text{ErFe}_{11}\text{Ti}$. This observation corroborates the lower M_{sat} value obtained at 300 K in the hydride. Another feature of the isofield magnetization curves is the minimum observed at low temperature.

FIG. 4. Isofield magnetization curves at different magnetic field on oriented c axis $\text{ErFe}_{11}\text{Ti}$ compounds in the 50–275 K temperature range.

This minimum occurs in the same temperature range as the spin reorientation T_{SR} does. The increase of the magnetization when cooling below T_{SR} may be associated to the progressive tilting of the Er magnetic moment apart from the c axis, thus leading to an increase of the net magnetization ($M_{\text{Fe}} - M_{\text{Er}}$). Another possibility would be a coherent rotation of M_{Fe} and M_{Er} , both remaining antiferromagnetically coupled, but with such a phenomena, a decrease of the projection of the magnetization along the c axis and a non-negligible remanent magnetization would be expected unlike what is experimentally observed. The proposed interpretation for the rotation of the Er magnetization will be checked by low temperature neutron diffraction experiments.

Neutron-diffraction measurements on TbCo_3B_2 , with the isotope ^{11}B , show ferromagnetic structure below 35(2) K. Ordered magnetic moments of Tb and Co were found to be in the basal planes directed parallel to each other. The Tb ordered moment is significantly smaller than its free-ion value. The Co ordered moment is nearly zero. Ac-susceptibility and SQUID magnetometer measurements agree with the neutron results. © 1998 American Institute of Physics. [S0021-8979(98)35511-5]

TbCo_3B_2 belongs to the $\text{R}_{n+1}\text{Co}_{3n+5}\text{B}_{2n}$ (R =lanthanide, $n=0, 1, 2, 3$, and ∞) family of compounds with $n=\infty$, which crystallize in the hexagonal CaCu_5 -type structure¹ (P6/mmm space group). In this compound cobalt atoms in the $2c$ site of the isostructural TbCo_5 are replaced by boron atoms (Fig. 1).

Magnetic and specific heat measurements on some of the RCO_3B_2 compounds (mainly $\text{R}=\text{Gd}$, Sm , and Dy)²⁻⁶ show ferromagnetic behavior. In these measurements the magnetic structure, as well as the relative contributions of the atoms to the ferromagnetic moment, cannot be deduced. In this work we determine the magnetic moments on the Tb and Co atoms using neutron-diffraction measurements. The magnetic values obtained from the neutron-diffraction data are compared with ac-susceptibility and SQUID magnetometer measurements.

Polycrystalline TbCo_3B_2 sample was prepared by arc melting the elements, using the ^{11}B isotope (99.5 a/o) in an argon atmosphere. The obtained button was annealed at 1073 K in vacuum for 120 h. A specimen from the sample was examined by x-ray diffraction and was found to be single phase. Neutron ($\lambda=240$ pm) diffraction measurements of ~ 16 g sample were performed at the IRR-2 reactor at RT (~ 295 K) and LT (~ 18 K). The diffractograms were analyzed using the Rietveld profile analysis (the FULLPROF program).⁷ Ac-susceptibility measurements were carried out from 8 K up to RT on a 0.126 g sample. The applied ac field is ~ 10 Oe. Magnetization measurements were carried out using a SQUID magnetometer from 5 K up to RT on a 0.028 g sample. Magnetic fields ranging from zero up to 50 kOe, were used in the magnetization measurements.

The RT neutron diffractogram of TbCo_3B_2 [Fig. 2(a)] is consistent with the hexagonal CaCu_5 -type structure. The lattice parameters, $a=505.3(5)$ pm, and $c=301.1(3)$ pm are in agreement with previous x-ray diffraction data.¹

The LT neutron diffractogram of TbCo_3B_2 shows an in-

crease in the intensities of the reflections in comparison with the RT diffractogram [Fig. 2(b)]. This increase in intensity is consistent with a ferromagnetic structure. Rietveld analysis of the LT diffractogram results in the existence of both Tb and Co ordered magnetic moments in the basal plane, parallel to each other. The magnetic form factors of the Tb and Co atoms are approximated by the exponentially decreasing function, $\exp[-C(\sin \theta/\lambda)^2]$. The C values used in the refinements were fixed to be 4.8×10^4 pm² for Tb, and 8.3×10^4 pm² for Co (Ref. 8). The refined Tb and Co ordered magnetic moments are $5.4(2) \mu_B$ and $0.13(7) \mu_B$, respectively.

The temperature dependence of the neutron integrated intensity of the $\{010\}$ reflections was measured (Fig. 3). The ordering temperature, T_f^{neut} , at which the intensity of the magnetic contribution to the $\{010\}$ reflections vanishes, is 35(2) K (Fig. 3).

In the measurement of the molar ac-susceptibility, χ_M , vs temperature, a large maximum in χ_M is shown, charac-

FIG. 1. Crystallographic unit cell of TbCo_3B_2 . The Tb, Co, and B atoms occupy the $1a$, $3g$, and $2c$ sites, respectively, in the space group P6/mmm (CaCu_5 -type structure).

FIG. 2. Neutron ($\lambda \approx 240$ pm) powder diffraction data (dots) and Rietveld refinement profile (line) of TbCo_3B_2 at (a) RT and (b) LT. RT reflections are consistent with the hexagonal CaCu_5 -type structure. Increase of these reflections at LT is consistent with ferromagnetic ordering of Tb and Co atoms in the basal plane, parallel to each other. Observed peaks due to Al sample holder contribution (at $\sim 62^\circ$ and 74°) were omitted.

teristic of ferromagnetic transition at T_f^{susc} (Fig. 4; Table I). Another transition is observed at T_o^{susc} (Fig. 4; Table I). Above 150 K the sample is paramagnetic, and the susceptibility adheres to the Curie-Weiss law (Fig. 4). The effective

FIG. 3. Integrated intensity of the $\{010\}$ reflections as a function of temperature for TbCo_3B_2 . The magnetic contribution vanishes at 35(2) K.

FIG. 4. Ac-magnetic-susceptibility of TbCo_3B_2 as a function of temperature (left ordinate) and its expansion in the temperature range 100–280 K (right ordinate).

magnetic moments, μ_{eff} , the paramagnetic Curie temperature, θ , and the enhanced Pauli paramagnetic susceptibility,⁵ χ_0 , are obtained by fitting the Curie-Weiss law, $(\chi_M - \chi_0)^{-1} = (2.83/\mu_{\text{eff}})^2 (T - \theta)$, to the observed data (Table I).

SQUID magnetometer measurements of the magnetic moment, M , vs temperature, in applied magnetic field $H = 1$ kOe, show similar results. Two transitions, at T_f^{SQUID} and at T_o^{SQUID} , are observed (Table I). Above 150 K the Curie-Weiss law is observed with the refined parameters summarized in Table I.

SQUID magnetometer measurements of M vs the magnetic field, H , show ferromagnetic behavior of the sample at 5 K (Fig. 5). The observed magnetic moment at $H = 50$ kOe is $6.2 \mu_B$. This moment is not saturated. The estimated saturated value is $\sim 6.9 \mu_B$. The linear relation between M and H at 90 K indicates a non-ferromagnetic state (Fig. 5).

The neutron diffraction method as a powerful tool for determination of the magnetic structure and the magnitude of magnetic moment is demonstrated in this work. Previously, the determination of the lanthanide and Co magnetic moments was achieved by using different assumptions about the moments in the family $\text{R}_{n+1}\text{Co}_{3n+5}\text{B}_{2n}$ (Refs. 2–6). Mainly, it was assumed that the Co atom is either nonordered magnetically² or has a small moment, which is antiparallel to the lanthanide moment.^{4,5} The latter assumption is based on results for heavy lanthanides in RCO_5 (Ref. 9).

TABLE I. Enhanced Pauli paramagnetic susceptibility,⁵ χ_0 , paramagnetic Curie temperature, θ , effective magnetic moment, μ_{eff} , and transition temperatures, T_f , and T_o , as obtained from ac-susceptibility (applied field $H = 10$ Oe) and SQUID ($H = 1$ kOe) magnetometer measurements.

Method	χ_0 (emu/mol)	θ (K)	μ_{eff} (μ_B)	T_f (K)	T_o (K)
ac-susceptibility	0.071(1)	40(4)	7.7(1)	35(5)	150(5)
SQUID	0.022(1)	14(7)	7.8(2)	35(5)	130(5)

FIG. 5. Magnetic moment as a function of magnetic field as measured using SQUID magnetometer at 5 and 90 K.

Our LT (18 K) neutron diffraction data requires $5.4(2) \mu_B$ for the magnetic moment of Tb, and $0.13(7) \mu_B$ for Co, with the moments aligned parallel to each other. Attempts to refine the neutron diffraction data using Co magnetic moment which is either zero or antiparallel to the Tb magnetic moment resulted in significantly worse agreement factors. Moreover, attempts to increase the Tb magnetic moment up to its free-ion value (i.e., $9 \mu_B$) show a clear disagreement with the experimental data.

The SQUID magnetometer measurements of M vs H (Fig. 5) agree with the reduced magnetic moment of Tb. Extrapolating $M \propto 1/H$ to $1/H=0$ resulted in $\sim 6.9(2) \mu_B$ for the saturated moment at 5 K. This value is higher than the neutron value [total moment of $5.8(2) \mu_B$] at LT (18 K). This is expected from the difference in the temperatures at which the moments were measured. Similar reduction of the lanthanide magnetic moment has been previously^{3,4} estimated from magnetization measurements for other lanthanides in this structure (e.g., Dy and Sm). This reduction was associated with crystalline electric field effects.^{3,4}

Above 150 K the TbCo_3B_2 compound exhibits the paramagnetic behavior, as determined from the SQUID and ac-susceptibility measurements (Table I). The discrepancy in χ_o and θ is ascribed to the difference in the applied field. The best-fitted effective magnetic moment is small in comparison with the free-ion Tb^{3+} effective moment ($9.72 \mu_B$). This result can probably be related to the reduction in the ordered magnetic moment discussed above.

The nature of the higher temperature transition, T_o , observed by both SQUID and ac-susceptibility measurements (Table I), is yet to be studied.

The Mössbauer spectra of a series of rhombohedral $\text{Tb}_2\text{Fe}_{17-x}\text{Si}_x$ solid solutions, with x equal to 0, 1, 2, and 3, have been measured as a function of temperature. Although the spectra of $\text{Tb}_2\text{Fe}_{17}$ change substantially upon cooling from 295 to 85 K, it has been possible to fit them with a consistent seven sextet model corresponding to a basal magnetization. The spectral analysis yields reasonable hyperfine parameters and the expected changes with temperature. The resulting weighted average effective iron recoil mass of 66 g/mol and the Mössbauer temperature of 395 K are typical of this type of intermetallic compound. In addition, the isomer shifts and the hyperfine fields observed for the crystallographically distinct iron sites in $\text{Tb}_2\text{Fe}_{17}$ agree well with those expected from the differences in the Wigner–Seitz cell volumes and the near-neighbor environments of the four sites. The spectra of the silicon substituted solid solutions have been fit with the same model and similar hyperfine parameters, but with a binomial distribution of near-neighbor environments. The weighted average hyperfine field decreases slowly with increasing silicon content, whereas the isomer shift increases. © 1998 American Institute of Physics. [S0021-8979(98)35611-X]

R_2Fe_{17} is a very common intermetallic phase whose magnetic properties can be modified by replacing part of the iron by a substitutional metal such as aluminum,^{1–4} gallium,^{5,6} or silicon.^{7,8} Often the Curie temperatures increase up to a maximum at $x \approx 3$ in these $\text{R}_2\text{Fe}_{17-x}\text{M}_x$ solid solutions. Thus a systematic study of these compounds may lead to improved permanent magnet materials as a result of a better understanding of the influence of the substitutional metal.

Herein, we report on the magnetic properties of $\text{Tb}_2\text{Fe}_{17}$ and its silicon substituted solid solutions, $\text{Tb}_2\text{Fe}_{17-x}\text{Si}_x$, with $x = 1, 2$, and 3 , by Mössbauer spectroscopy between 85 and 295 K. We are interested in these solid solutions because their lattices contract with increasing x , contractions which are rather surprising because it has generally been believed that such contractions would lead to an increase in the anti-ferromagnetic coupling between some of the iron atoms. Such an increase should lead to a decrease in the Curie temperature in contrast to the observed increase with x . Thus a study of these compounds, which seem to be an exception to this general belief, may help to better understand the magnetic behavior of such substituted intermetallic compounds.

The $\text{Tb}_2\text{Fe}_{17-x}\text{Si}_x$ solid solutions, with $x = 0, 1, 2$, and 3 , were prepared as described previously.⁵ Powder x-ray diffraction results indicate that all of these compounds are virtually single phase and crystallize with the rhombohedral $\text{Tb}_2\text{Zn}_{17}$ -type structure. Three silicon atoms per formula unit are the most that can be introduced into $\text{Tb}_2\text{Fe}_{17}$ and still yield a single phase solid solution.

The Mössbauer spectral absorbers contained 27 mg/cm² of powder¹⁰ which had been sieved to a particle diameter of

0.045 mm or less. The Mössbauer spectra were measured on a constant acceleration spectrometer which utilized a rhodium matrix cobalt-57 source and was calibrated at room temperature with an α -iron foil.

A preliminary study¹¹ of the Mössbauer spectra of $\text{Tb}_2\text{Fe}_{17}$ at 78 and 295 K has revealed a distinct difference in the shape of the spectra at these two temperatures. Further, the reported temperature dependence of the spectral hyperfine parameters was unusual. In order to better understand these changes, the $\text{Tb}_2\text{Fe}_{17}$ Mössbauer spectra were remeasured at several temperatures between 85 and 295 K. Figure 1, which shows several of these spectra, reveals a continuous change in the shape of the spectrum upon cooling. At 85 K the spectrum shows a very distinct absorption at ca. -5.3 mm/s as well as two distinct shoulders at ca. -2.5 and 4.5 mm/s, absorptions which begin to converge with others above 175 K such that at 295 K there is little if any sign of these three spectral features.

Because the magnetization of $\text{Tb}_2\text{Fe}_{17}$ is basal, we have fit its Mössbauer spectra with a seven sextet model⁹ in which the hyperfine parameters are consistent with both the near-neighbor environment and the Wigner–Seitz cell volume of each iron site. The seven sextets correspond to the seven inequivalent magnetic sites,⁹ $6c, 9d_6, 9d_3, 18f_{12}, 18f_6, 18h_{12}$, and $18h_6$, respectively, and the isomer shifts for the crystallographically equivalent, but magnetically inequivalent, sites were constrained to be equal. Further, in this model the isomer shift increases with the cell volume of a crystallographic site because of a reduced s -electron density at the iron-57 nucleus. The results of these fits are given in Table I along with the 295 K Wigner–Seitz cell volume for each site.^{12,13}

FIG. 1. The Mössbauer spectra of $\text{Tb}_2\text{Fe}_{17}$ measured at 295, 225, 175, and 85 K, and the 85 K Mössbauer spectra of the $\text{Tb}_2\text{Fe}_{17-x}\text{Si}_x$ solid solutions with $x=1, 2$, and 3.

As already observed⁹ in many related R_2Fe_{17} compounds, the hyperfine fields increase with the number of iron near neighbors for each crystallographic site, see Fig. 2. As expected, the hyperfine fields decrease with increasing temperature and the quadrupole shifts are independent of temperature. The effective mass, M_{eff} , of each iron site can be calculated¹⁴ from the temperature dependence of the isomer shift. Table I reveals that the 9d site has the largest, the 18f and 18h sites have similar intermediate, and the 6c site has

FIG. 2. The correlation between the $\text{Tb}_2\text{Fe}_{17}$ site weighted average hyperfine fields and the number of iron near-neighbors.

the smallest effective masses. This indicates that the 9d site is more covalently bound than the other sites, as is expected for the site with the smallest Wigner-Seitz cell volume. The temperature dependence of the isomer shift and the logarithm of the spectral absorption area may be used to calculate¹⁴ the Mössbauer temperature, θ_M , for each site. The resulting values, of ca. 400 K, see Table I, are typical for this type of intermetallic compound.¹⁵

^aThe linewidth is 0.32 mm/s at 295 K and 0.29 mm/s at 85 K and $d(\ln \text{Area})/dT$ is $-7.51 \times 10^{-4} \text{ K}^{-1}$.

^bRelative to room temperature α -iron foil.

^c δ_0 is the zero Kelvin intercept and the slope, $d\delta/dT$, is $\times 10^{-4} \text{ (mm/s)/K}$.

^dCalculated with the structural parameters given in Ref. 13 and BLOKJE, Ref. 12, with the 12 coordinate atomic radii of 1.80 and 1.26 Å for terbium and iron, respectively.

The Mössbauer spectra of Tb₂Fe_{17-x}Si_x, with $x = 1, 2$, and 3, were measured between 85 and 295 K, and the 85 K spectra are shown in Fig. 1. These spectra are clearly much broader than those of Tb₂Fe₁₇ and thus must be fit with a distribution of hyperfine fields resulting from the binomial distribution of silicon near neighbors, a fitting procedure which has been described in detail elsewhere.^{8,11} To carry out these fits, the amount of silicon on each iron site must be known. Unfortunately, at this time, no neutron diffraction results are available for these compounds, and thus the silicon occupancies reported⁸ for Ce₂Fe_{17-x}Si_x were used herein. Indeed, earlier work¹⁻⁸ has shown that the M site occupancies are rather independent of the nature of the rare earth in R₂Fe_{17-x}M_x. Further, for low silicon content even less variation with the rare earth is expected. A single linewidth, between 0.29 mm/s at 85 K and 0.32 mm/s at 295 K, was used in the fits.

The resulting isomer shifts follow the sequence $9d < 18f < 18h < 6c$ as observed in Tb₂Fe₁₇. Figure 3 shows the temperature dependence of the average isomer shift for the four compounds studied herein. It is clear that the 85 K weighted average isomer shift increases with silicon content from 0.038 mm/s at $x = 0$ to 0.112 mm/s at $x = 3$. A similar variation was observed^{7,8} in Nd₂Fe_{17-x}Si_x and Ce₂Fe_{17-x}Si_x. Figure 3 shows the temperature dependence of the weighted average hyperfine field. The decrease in the hyperfine field, ΔH , due to each silicon near neighbor at a given site, is ca. 16 kOe, a value^{7,8} which is typical of these solid solutions.¹⁵

The temperature dependence of the spectral hyperfine parameters, and their changes with x in Tb₂Fe_{17-x}Si_x, show an internal consistency in the series, agree well with previous results¹⁻⁸ obtained for similar R₂Fe_{17-x}M_x solid solutions, and agree with the magnetization measurements,¹³ measurements which indicate a maximum Curie temperature of 520 K for Tb₂Fe₁₄Si₃. This consistency will be discussed in detail in a future paper.¹³

In the experimental section, it was noted that a maximum of three silicon atoms per formula unit can be introduced into Tb₂Fe₁₇. In the fits of Tb₂Fe₁₄Si₃, a doublet with an isomer shift of 0.2 mm/s, a quadrupole splitting of 0.19

mm/s, and a relative area of 4%, had to be included at 85 K. Its parameters are consistent with the iron-silicon phase previously observed⁷ in Nd₂Fe_{17-x}Si_x. Both the formation of this stable impurity phase and the contraction of the unit cell lattice with increasing x may explain why no more than three silicon atoms can be substituted into Tb₂Fe₁₇.

Asymmetric nonlinear magneto-optic effects in PtMnSb thin films

R. Carey,^{a)} D. M. Newman, and M. L. Wears

Centre for Data Storage Materials, Coventry University, Coventry CV1 5FB, United Kingdom

Nonlinear magneto-optic measurements on thin films of PtMnSb exhibit asymmetric behavior in both the transverse and longitudinal Kerr configurations. Second harmonic generation under magnetization reversal is asymmetric about the state of zero magnetization with the degree of asymmetry dependent on the angle of incidence. The origin of the asymmetry arises from simultaneous detection of even ($\propto M^2$) and odd ($\propto M$) magneto-optic effects. In principle such effects exist in both the optical linear and nonlinear regimes but in most materials even effects are very small and only observed in specific experimental arrangements where the linear effects in M vanish (such as the Voigt configuration). This is not the case with PtMnSb in which the band structure produces total polarization of the majority and minority spin carriers giving rise to unusually strong magneto-optic interactions. © 1998 American Institute of Physics.

[S0021-8979(98)44411-6]

INTRODUCTION

Pustogowa, Hubner, and Bennemann^{1,2} calculate magneto-optic effects in second harmonic generation (SHG) arising from the nonlinear interaction between an optical field and a magnetized medium. They show that such effects may be significantly larger than their linear counterparts. From quite general results they consider the possibility that materials with large spin-orbit coupling or large magnetic moments as in the Heusler alloys might exhibit large Kerr rotations in the second harmonic. Such expectations were subsequently confirmed experimentally for single crystals of Fe,³ Fe/Cu,⁴ and Rh/Co/Cu (Ref. 5) multilayers and also for the Heusler alloy PtMnSb.⁶

PtMnSb is a half-metallic ferromagnet that, in its crystalline stoichiometric form, exhibits the largest magneto-optic effects yet recorded at room temperature. In most experimental configurations the changes observed in a linear optical field reflected from or transmitted through the medium being subjected to magnetization reversal are typically an order of magnitude greater than those observed for iron. Following Pustogowa *et al.* magneto-optic effects observed in the SHG field from PtMnSb are expected to be larger still. Reif, Rau, and Matthias,⁶ reporting the only nonlinear magneto-optic studies of PtMnSb to date, investigated circular magnetic dichromism and the longitudinal Kerr effect at one angle of incidence (75°) for the (111) surface of a single crystal. On reversal of the magnetization they recorded a 7% change in detected SHG intensity for circularly polarized radiation and a Kerr rotation of 14° for linearly polarized radiation.

Following our previous extended studies of thin films of PtMnSb,⁷⁻¹⁰ this article reports our recent investigation of

the nonlinear magneto-optic behavior of thin films of PtMnSb in the transverse Kerr configuration. In addition, the circular dichroism measurements reported by Reif *et al.* are repeated and extended to other angles of incidence.

In the linear optical regime it is usual to describe the magneto-optic interaction, in the transverse Kerr configuration, in terms of δ , the fractional change in the detected reflected intensity, defined as

$$\delta = \frac{I_{Ms}^{\uparrow} - I_{Ms}^{\downarrow}}{I_{Ms}^{\uparrow} + I_{Ms}^{\downarrow}},$$

where I_{Ms}^{\uparrow} and I_{Ms}^{\downarrow} are the intensities associated with opposite states of in-plane magnetic saturation, normal to the plane of incidence. This definition can similarly be used to describe transverse Kerr effects nonlinear in the optical field:

$$\delta_{\text{SHG}} = \frac{Y_{Ms}^{\uparrow} - Y_{Ms}^{\downarrow}}{Y_{Ms}^{\uparrow} + Y_{Ms}^{\downarrow}}$$

where Y_{Ms}^{\uparrow} and Y_{Ms}^{\downarrow} are now the detected SHG yields associated with the opposite states of magnetic saturation. In both the linear and nonlinear cases the detected intensity changes are expected to be symmetrical about the reflected intensity or SHG yield when the sample magnetization is zero along a direction perpendicular to the plane of incidence, $I_{M=0}$ and $Y_{M=0}$, respectively. Note that because the structure of PtMnSb is noncentrosymmetric the SHG yield will contain both bulk and surface contributions.

EXPERIMENT

The PtMnSb films used in this study were prepared by magnetron sputtering from individual targets of Pt and MnSb (50:50 at. %) onto a rotating substrate. As deposited, the films were amorphous and were subsequently crystallized by rapid thermal processing (RTP) in vacuum using a

^{a)}Electronic mail: r.carey@coventry.ac.uk

FIG. 1. Asymmetry in the SHG yield under magnetization reversal in the transverse Kerr configuration.

60 W CO₂ laser. X-ray diffraction analysis showed the resulting samples to be composed of very fine crystallites with the (111) surface predominant. With a thickness of 190 nm the films were just semitransparent. In the linear magneto-optic regime they exhibited a polar Kerr rotation of 1.8° at a wavelength (λ) of 670 nm and in the transverse Kerr configuration a fractional change in reflected intensity of 2.5% at $\lambda = 532$ nm.

Nonlinear magneto-optic measurements were made using a Minilite Nd:Yag ($\lambda = 1064$ nm) laser emitting Q-switched 5 ns, 25 mJ pulses at a repetition rate of 10 Hz to produce a power density of 70×10^6 W cm⁻² at the film surface. Appropriate filters were used to block SHG signals produced by the input optical train and also to isolate the fundamental from the photomultiplier detector.

Prior to making magneto-optic measurements the polarization of the SHG signal from a demagnetized sample was studied as a function of the polarization of the 1064 nm (fundamental) beam. The SHG yields Y_{Ms}^{\uparrow} , Y_{Ms}^{\downarrow} , and $Y_{M=0}$ were then recorded as a function of the angle of incidence using *p*-polarized radiation in the transverse configuration and both left and right circularly polarized beams in the longitudinal configuration. The values presented for these parameters are averages obtained over 500 pulses recorded using a Lecroy digital oscilloscope.

RESULTS AND DISCUSSION

In the polarization studies from demagnetized samples we found, as previously observed by Reif, Rau, and Matthias,⁶ that the SHG output beam was *p* polarized for both *p* and *s* input polarization. The efficiency of the SHG process was, however, greatly reduced when the fundamental input beam was *s* polarized.

Figure 1 shows the behavior of the SHG ($\lambda = 532$ nm) yield under magnetization reversal in the transverse Kerr configuration as a function of angle of incidence. The yield

FIG. 2. Asymmetric changes in SHG yield for left circularly polarized radiation in the longitudinal Kerr configuration.

for the two states of magnetic saturation is seen to be quite asymmetrical about that of the demagnetized state. The transverse effect with *s*-polarized input radiation is not actually forbidden in the SHG field as it is for the linear field but no measurable magneto-optic interaction was observed.

The asymmetry is also apparent in the longitudinal configuration. Figure 2 shows the results taken using left circularly polarized input radiation. Essentially identical results are obtained using right circularly polarized radiation. A similar asymmetry is just discernible in the raw data of Reif, Rau, and Matthias.⁶ Using the definition of Reif *et al.* for the fractional change (Δ) in detected intensity due to circular magnetic dichroism we obtain values for Δ greater than 42% at 60° angle of incidence. This is considerably larger than the 7% they reported at a wavelength of 266 nm and a 75° angle of incidence. The difference is probably a conse-

FIG. 3. Magnetic hysteresis loop of the sample used for the nonlinear magneto-optic experiments.

FIG. 4. Odd and even contributions to the fractional intensity change in the SHG field as a result of magneto-optic interactions observed in the transverse Kerr configuration.

quence of the different wavelengths at which the measurements are made and of possible enhancement within the thin film structure of our samples.

In discussing nonlinear magneto-optic effects most workers assume quadrupole interactions to be negligible and, following Pan, Wei, and Shen,¹¹ separate the geometry dependent elements of the dipole nonlinear susceptibility tensor into two classes, odd and even with respect to magnetization (\mathbf{M}) reversal about a given direction. There is often a tendency to assume that even susceptibility elements are small and may be ignored or incorporated with the nonmagnetic contribution to the nonlinear susceptibility.³ With most of the simple ferromagnetics the former assumption is valid as evidenced by the magnetic hysteresis loops recorded for Fe (Ref. 3) and Co/Cu (Ref. 12) multilayers using the nonlinear Kerr effect. Any significant \mathbf{M}^2 or higher (even) order in \mathbf{M} contribution to the detected SHG signal would distort the hysteresis loops obtained. For the PtMnSb films reported here it is clear that, although the magnetic behavior of the samples is perfectly conventional (see Fig. 3), the detected SHG signal is not a simple linear function of sample magnetization for either the transverse or the longitudinal configurations. The presence of a significant even ($\propto \mathbf{M}^2$) contribution to the detected signal immediately explains the

asymmetric nature of the results of Figs. 1 and 2. Assuming the odd ($\propto \mathbf{M}$) contribution to the yield is symmetrical about the $Y_{M=0}$ yield, separation of the odd and even contributions is straightforward and fractional changes in the SHG yield of each component are readily achieved. These are shown in Fig. 4 where odd ($\delta(M_{\text{odd}})$) and even ($\delta(M_{\text{even}})$) contributions to the observed δ_{SHG} are plotted as a function of angle of incidence.

It can be seen that the odd and even contributions are very large (cf. 25%) and of similar magnitude. Both the odd and even contributions in the nonlinear (SHG) field are at least an order of magnitude greater than those observed in linear field measurements. To our knowledge values $>50\%$ for the fractional change in any even (\mathbf{M}) magneto-optic effects are hitherto unreported. It therefore seems very likely that even (\mathbf{M}) magneto-optic effects in the linear field measurements for PtMnSb will also be large. Our initial measurements indicate that this is indeed the case and odd and even effects again contribute to the detected signal.

CONCLUSION

Asymmetry in the magneto-optic transverse Kerr effect in second harmonic generation from PtMnSb thin films has been shown to originate in signals that are odd and even in the sample magnetization and comparable in size. Magneto-optic effects in PtMnSb are measured to be at least an order of magnitude greater in the SHG field than in the normal linear field as was predicted by Pustogowa *et al.*¹ The measurements of the even (\mathbf{M}) components in the SHG field are believed to be the first of their kind to be reported.

The magnitude of the polar magneto-optical Kerr effect in reflection from thick iron epitaxial films is experimentally found to strongly depend on the crystallographic orientation of the film, with variations of more than 20%. Similar results are obtained on the (001) and (110) faces of a bulk Fe crystal. It is shown that this anisotropy can be described as a third-order effect in the magnetization \mathbf{M} on the optical response $\epsilon(\omega, \mathbf{M})$. Our analysis can also be used to understand the transversal Kerr effect at normal incidence recently observed by Gridnev *et al.* © 1998 American Institute of Physics. [S0021-8979(98)46611-8]

Magneto-optics provides a simple and quite universal way to probe the magnetization \mathbf{M} of a ferromagnetic medium.¹⁻⁴ Most of the magneto-optical phenomena arise due to the effect of \mathbf{M} on the dielectric constant of a medium $\epsilon(\mathbf{M})$. Assuming that this effect is weak, the $\epsilon(\mathbf{M})$ dependence is often expanded in powers of \mathbf{M} yielding⁵

$$\vec{\epsilon}(\mathbf{M}) = \vec{\epsilon}^{(0)} + 4\pi i \mathbf{f} \cdot \mathbf{M} + 4\pi \mathbf{g} : \mathbf{M}\mathbf{M} + 4\pi i \mathbf{h} : \mathbf{M}\mathbf{M}\mathbf{M} + \dots, \quad (1)$$

where $\epsilon^{(0)}$ denotes the magnetization-independent part of $\epsilon(\mathbf{M})$ and the tensors \mathbf{f} , \mathbf{g} , and \mathbf{h} describe the linear-, second-, and third-order magnetization-induced corrections to the dielectric function of the magnetic medium. So far the main attention has been paid to the magneto-optical effects arising via the second and third term in Eq. (1). For instance, to describe magnetic circular dichroism (MCD) it is usually enough to account for the term $4\pi i \mathbf{f} \times \mathbf{M}$ that is linear in the magnetization. Upon light reflection, MCD results in the magneto-optical Kerr effect (MOKE) which is used to study magnetism in opaque media.¹ The second-order magnetization-induced term $4\pi \mathbf{g} : \mathbf{M}\mathbf{M}$ results in the linear birefringence.² Higher order terms in \mathbf{M} in Eq. (1) are usually neglected. However, they may result in new magneto-optical effects and thus become important. In particular, a third-order contribution ($\propto \mathbf{h}$) to Eq. (1) has been recently observed by Gridnev *et al.*⁶ to contribute to the transversal magneto-optical Kerr effect upon light reflection from the (111) face of LiFe_5O_8 .

In this work we analyze novel magneto-optical effects that can originate via higher-order (and anisotropic) contributions in the magnetization dependence of the dielectric response in cubic media. In particular, these contributions can describe experimentally observed anisotropy of the magneto-optical Kerr rotation in reflection from (001) and

(110) oriented iron epitaxial films and (001) and (110) faces of a bulk Fe crystal. A similar effect has also been observed on epitaxial hcp Co films,³ where the anisotropy is linear in the magnetization.^{3,4} For cubic bcc iron, however, this linear effect is forbidden by symmetry and the anisotropy can be understood as a third-order effect of the magnetization. We also demonstrate how the orientation dependence of the polar MOKE is related to the transversal third-order MOKE observed in Ref. 6.

The epitaxial Fe(001) and (110) films with the thickness 700–1000 Å were grown on Au(001) and Au(111) buffer layers as described in Ref. 7. The bulk samples were prepared by cutting an iron single crystal along (001) and (110) planes with subsequent polishing by a diamond paste. The MOKE spectra of epitaxial Fe films were measured in the range of 4–10 eV using the synchrotron facility described in Ref. 8. Similar measurements in the range 1.55–6 eV on epitaxial films and bulk samples were done on a Kerr spectrometer.

In Fig. 1 we show the spectra of the Kerr rotation angle ϕ_K and the Kerr ellipticity η_K measured on thick Fe epitaxial films with the (001) and (110) orientation. A strong anisotropy $\Delta\phi_K = \phi_K^{(001)} - \phi_K^{(110)}$ and $\Delta\eta_K = \eta_K^{(001)} - \eta_K^{(110)}$ is

FIG. 1. The Kerr rotation (left panel) and Kerr ellipticity (right panel) spectra measured on epitaxial Fe(001) and Fe(110) films.

^{a)}On leave from the Institute of Crystallography, Moscow, Russia; electronic mail: petukhov@sci.kun.nl

FIG. 2. The same as in Fig. 1 but measured on two faces of a bulk iron crystal.

clearly seen. For the thick Fe films the effect of quantum well states should be negligible and the natural explanation of this anisotropy could then be a difference in the structure of the two studied films. For instance, a different strain of the Fe lattice may affect the magneto-optical parameters. Alternatively, one can think about a different roughness of the different film surfaces as a possible source of the orientation dependence of MOKE.

However, an additional study performed on different faces of iron bulk single crystals contradicts this simple explanation. In Fig. 2 we show the MOKE spectra measured upon light reflection from Fe(001) and Fe(110). In this case the effect of the lattice strain should be much smaller, if not negligible, in comparison to that expected in epitaxial films. The surface (micro-) roughness of the faces of the bulk crystal, which can result from the sample polishing, is obviously expected to be distinctly different from the surface (micro-) roughness of epitaxial films which can arise during the film growth. However, the great similarity between the results presented in Figs. 1 and 2 is obvious. Only at small photon energies $\hbar\omega \leq 2$ eV there is a clear anisotropy found for the epitaxial films while the single crystal faces do not show this. This observation strongly suggests that the MOKE anisotropy at $\hbar\omega > 2$ eV is an intrinsic effect of a perfect Fe crystal rather than related to the mechanisms described above.

For cubic media the first two tensors $\vec{\epsilon}^{(0)}$ and \mathbf{f} in the expansion (1) reduce to scalars ϵ_0 and f_0 times the unity symmetric and antisymmetric tensors, respectively. Therefore, up to the term linear in the magnetization, the relation between the induction $\mathbf{D}(\omega)$ and the electric field $\mathbf{E}(\omega)$ of the light wave can be written in a vector form:

$$\mathbf{D} = \epsilon_0 \mathbf{E} + 4\pi i f_0 \mathbf{E} \times \mathbf{M}. \quad (2)$$

Although MCD depends on the mutual orientation of the light propagation direction and the magnetization \mathbf{M} , within the approximation of Eq. (2) MCD is isotropic in a sense that it does not depend on the orientation of \mathbf{E} and \mathbf{M} relative to the crystallographic axes. Therefore, to describe the anisotropic MCD effect in a cubic medium one has to account for the higher-order terms in the expansion (1), which are *anisotropic* even in high-symmetry cubic media. The second-order term $4\pi g_{ijkl} M_k M_l$ is even in the magnetization and therefore cannot contribute to MCD. In order to account for the anisotropy of MCD one therefore has to consider the third-order term.

In general, an axial fifth-rank tensor in a cubic medium has ten independent nonvanishing elements.⁹ The permutation symmetry of h_{ijklm} with respect to the last three indices and the Onsager symmetry $h_{ijklm} = -h_{jiklm}$ reduces this number to only 2. In the following it is convenient to introduce a contracted notation. We define a ten-dimensional vector \mathbf{MMM} with components

$$\mathbf{MMM} = \begin{pmatrix} M_1^3 \\ M_2^3 \\ M_3^3 \\ 3M_2 M_3^2 \\ 3M_3 M_1^2 \\ 3M_1 M_2^2 \\ 3M_3 M_2^2 \\ 3M_1 M_3^2 \\ 3M_2 M_1^2 \\ 6M_1 M_2 M_3 \end{pmatrix}, \quad (3)$$

where M_1 , M_2 , and M_3 denote the projections of \mathbf{M} on the principal crystallographic axes [100], [010], and [001]. The axial fifth-rank tensor \mathbf{h} can then be written as a third-rank tensor κ_{ijk} where the last index K runs from 1 to 10. The nonvanishing elements of κ_{ijk} are

$$\kappa_1 \equiv \kappa_{123} = \kappa_{231} = \kappa_{312} = -\kappa_{132} = -\kappa_{213} = -\kappa_{321}, \quad (4)$$

$$\begin{aligned} \kappa_2 \equiv \kappa_{127} = \kappa_{238} = \kappa_{319} = -\kappa_{139} = -\kappa_{328} = -\kappa_{217} \\ = \kappa_{125} = \kappa_{236} = \kappa_{314} = -\kappa_{134} = -\kappa_{326} = -\kappa_{215}. \end{aligned}$$

For isotropic media the same elements of κ_{ijk} are nonvanishing but the number of independent elements is reduced to one because of an extra relation $\kappa_1 = 3\kappa_2$ between the κ_1 and κ_2 elements. In cubic media the anisotropic element $\kappa_{an} = \kappa_1/3 - \kappa_2 \neq 0$ leads to the anisotropy in MCD.

Now we introduce the laboratory coordinate system (xyz), where the z axis is normal to the surface and along the magnetization vector $\mathbf{M} = \mathbf{e}_z M$. The transformation matrix \mathbf{A} from the crystallographic (123) to the laboratory (xyz) frame is taken in the form

$$\mathbf{A} = \begin{pmatrix} \cos \theta \sin \psi & \cos \theta \cos \psi & -\sin \theta \\ -\cos \psi & \sin \psi & 0 \\ \sin \theta \sin \psi & \sin \theta \cos \psi & \cos \theta \end{pmatrix}, \quad (5)$$

where the angles θ and ψ determine the orientation of the surface normal \mathbf{e}_z with respect to the crystallographic axes. Using Eqs. (4) and (5) one can find the xy element of $\vec{\epsilon}(\mathbf{e}_z M)$:

$$\begin{aligned} \epsilon_{xy}(\mathbf{e}_z M) = 4\pi i [f_0 M + \kappa_1 M^3 - 6\kappa_{an} \sin^2 \theta (\cos^2 \theta \\ + \sin^2 \theta \cos^2 \psi \sin^2 \psi) M^3] \end{aligned} \quad (6)$$

that determines the MCD for light propagating along z . The last term in Eq. (6) is *anisotropic*, i.e., it depends on the orientation of the surface relative to the cubic frame. For the (001) face $\theta = 0$ and Eq. (6) yields

$$\epsilon_{xy}^{(001)}(\mathbf{e}_z M) = 4\pi i [f_0 M + \kappa_1 M^3] \quad (7)$$

while for the (110) face $\theta = \pi/4$, $\psi = 0$ and

$$\epsilon_{xy}^{(110)}(\mathbf{e}_z M) = 4\pi i [f_0 M + \kappa_1 M^3 - \frac{3}{2} \kappa_{an} M^3]. \quad (8)$$

Obviously, $\epsilon_{xy}^{(001)} \neq \epsilon_{xy}^{(110)}$ and the third-order term in expansion (1) can describe the observed anisotropy.

The analysis above can also be used to describe the observed third-order *transversal* ($\mathbf{k} \perp \mathbf{M}$, where \mathbf{k} denotes the light wave vector) Kerr effect reported in Ref. 6. We take the light incident along the surface normal z and the magnetization parallel to the surface $\mathbf{M} = \mathbf{e}_x M$. In cubic media the linear in the magnetization contribution $i f_0 \mathbf{E} \times \mathbf{M}$ to the induced polarization is then always along \mathbf{k} and, therefore, does not radiate into the direction of light propagation. The second-order contribution $\mathbf{g}:\mathbf{M}\mathbf{M}$ is reciprocal and cannot contribute to the MCD and one again arrives to the third-order term which gives rise to the transversal MCD via

$$\epsilon_{xy}(\mathbf{e}_x M) = h_{xyxxx} M^3, \quad (9)$$

where $h_{xyxxx} = \kappa_{an} f(\theta, \psi, \phi)$ denotes the magnitude of the corresponding tensor element in the laboratory coordinate system which depend on the relative orientation of the two frames given by the Euler angles θ , ψ , and ϕ , where the additional angle ϕ describes the azimuthal orientation of the sample which becomes important for the transversal geometry. We note that this transversal MCD vanishes on the even-fold rotation symmetry (001) and (110) faces of cubic fcc and bcc crystals. Indeed, the rotation of the sample by π reverses the direction of $\mathbf{M} = \mathbf{e}_x M$ while ϵ_{xy} and h_{xyxxx} should be unchanged since $(x, y) \rightarrow (-x, -y)$ is a symmetry operation for these faces and $\epsilon_{xy}(\mathbf{e}_x M)$ should therefore vanish for any ϕ . For other faces the transversal MCD is present. For instance, for the (111) face one can calculate the function $f(\theta, \psi, \phi)$ to obtain

$$\epsilon_{xy}(\mathbf{e}_x M) = -\frac{4\pi i}{\sqrt{2}} \kappa_{an} M^3 \sin 3\phi. \quad (10)$$

Note that this effect is anisotropic during azimuthal rotation

of the sample. It vanishes every time when the magnetization is normal to one of the mirror symmetry planes (011), (101), and (110) of the (111) face. Comparing Eqs. (7), (8), and (10) one can see that a measurement of the transversal MOKE on Fe(111) similar to that done by Gridnev *et al.*⁶ can be used for an unambiguous verification of the mechanism of the anisotropy of the polar Kerr effect proposed in this work.

In conclusion, we have observed a strong surface orientation dependence of the magneto-optical Kerr effect in the polar configuration that can be understood as a third-order effect in the magnetization on the optical response. We give a phenomenological description of this effect, which can also explain the transversal Kerr effect at normal incidence on odd-fold symmetry faces of a cubic crystal observed by Gridnev *et al.*

Magneto-optical properties of MnPt_3 : LDA+ U calculations

R. F. Sabiryanov and S. S. Jaswal^{a)}

*Department of Physics and Astronomy and Center for Materials Research and Analysis,
University of Nebraska, Lincoln, Nebraska 68588-0111*

Our recent first-principle LMTO-ASA calculations of the magneto-optical properties of MnPt_3 are in good agreement with the experimental data. However, the calculated positions of the Kerr-rotation peaks are shifted by approximately 0.5 eV with respect to the experimental results. An interesting feature in the density of states (DOS) of MnPt_3 is the narrow unoccupied peak in the minority Mn d DOS signifying the fairly localized nature of these states. Usually the study of the optical properties of systems with localized states requires the inclusion of correlation effects beyond the LDA through the Hubbard U parameter. We report here a study of the effect of U and the energy expansion parameter E_v in LMTO for the minority Mn d states on the calculated Kerr spectra of MnPt_3 . It is found that a reasonable choice of E_v gives the Kerr effect in good agreement with the experimental data without the need to use the U parameter. © 1998 American Institute of Physics. [S0021-8979(98)21811-1]

I. INTRODUCTION

Ferromagnetic compounds containing manganese and platinum have attracted considerable interest recently because of their large Kerr rotation. MnPt_3 and MnPtSb have Kerr rotation of 1.2° at 1.2 and 1.7 eV photon energies, respectively. The first-principle calculations of the Kerr effect in these compounds have been performed by a number of authors during the last three years using the local density approximation (LDA).¹⁻³ The calculated Kerr rotation as a function of the photon energy is in good agreement with the experiment. However, the position of the main peak, mentioned above, is shifted to the lower photon energy by 0.4–0.7 eV. The reasons for this shift are not well understood. The densities of states (DOS) of these compounds are similar. Both have large localized peaks of unoccupied states above the Fermi energy in the minority Mn d DOS well separated from the occupied states. The results of the electronic structure calculations show that MnPtSb in the ground state is half-metallic, i.e., it has a gap at the Fermi energy (E_F) in the minority spin states and no gap for majority spin states.¹⁻³ MnPt_3 is almost half-metallic with very low minority DOS around E_F .¹ It is well known that LDA fails to describe properly the optical properties of systems with highly localized states. Recently, LDA+ U approach has been used to get an improved description of the properties of some of the systems with localized states, where the Hubbard parameter U simulates correlations beyond the LDA.⁴ Another important parameter is the energy E_v about which expansion is carried out in the linear-muffin-tin-orbital (LMTO) method. Normally, E_v corresponds to the center of mass of the occupied states for a given orbital. Since the minority Mn d DOS primarily consists of a fairly localized and unoccupied band, the E_v should be the center of mass of the whole minority d band. This was not done in our earlier calculations. Therefore we study here the effect of U and E_v

for the minority Mn d band on the calculated Kerr rotation of MnPt_3 and the results are compared with the experimental data.

II. METHOD

The LMTO method in the atomic sphere approximation (LMTO-ASA) is used to perform the self-consistent spin-polarized electronic structure calculations for all results presented here, where the spin-orbit interaction is included in quasiperturbative manner.⁵ The details of the electronic structure calculations and procedure to calculate the Kerr effect are given in Ref. 1. The lifetime parameter for the interband contribution (\hbar/τ) is 0.4 eV. The collision frequency parameter (\hbar/γ) and the plasma frequency ($\hbar\omega_p$) are 0.3 and 4.4 eV, respectively. The procedure to calculate the U parameter is quite standard and a complete description can be found in Ref. 6. The calculated U parameter is included in the LMTO code to take into account the correlation effects beyond the LDA.^{4,6}

III. RESULTS AND DISCUSSION

Our recently calculated Kerr spectra for MnPt_3 obtained using the LDA show a good agreement with experimental data except for an overall shift of about 0.5 eV.¹ The present study is an attempt to improve upon this disagreement by the modifications to the calculational procedure commensurate with the electronic structure of this system. As mentioned in the introduction, we explore here the effect of E_v and U on the Kerr spectra of MnPt_3 .

The main contribution to Kerr effect at low energies is due to the p – d transitions on Pt sites. The effect of the Mn atoms is to provide large exchange splitting. If the spin-flip transitions are neglected, the contributions from minority and majority spin channels can be found and this analysis shows that the Kerr effect is determined mostly by the majority spins for energies below 1.3 eV and by the minority spins above this energy. This effect is due to the peculiarities of

^{a)}Electronic mail: sjaswal@unlinfo.unl.edu

FIG. 1. Kerr rotation and ellipticity of MnPt_3 : Theory—solid line gives the results with E_v at the center of mass of the whole minority Mn d band and dashed line with E_v at the center of mass of the occupied band; experiment—triangles represent the 95 K data from Ref. 1 and crosses represent the room temperature experimental results from Ref. 7.

the electronic structure. Minority band has a very narrow localized peak about 1.5 eV above the Fermi energy. This peak is determined mainly by the Mn d states, but Pt p and d states also have peaks at this energy due to the hybridization effect. Majority spins have very small DOS in this energy region.

The calculated Kerr spectra for two values of E_v are compared with the experimental data in Fig. 1. The dashed line corresponds to our earlier spectra that are shifted with respect to the experimental data by ~ 0.5 eV. This is based on the E_v that is the center of mass of the occupied minority Mn d band. Because this band is mostly unoccupied, a better choice of E_v is the center of mass of the whole band. This produces an upward shift of E_v by 3.44 eV. The solid line in Fig. 1 is based on this value of E_v and is in much better agreement with the experimental data than that based on the previous choice of E_v . With the new E_v magnetic moment changes from 3.6 to $3.66\mu_B$.

In an attempt to further improve the agreement between theory and experiment, we use the LDA+ U Hamiltonian where U is for the Mn d states. The U parameter is calculated using constrained LMTO formalism in the atomic limit.⁶ The value of U for the d^5 and d^6 configurations are 5.7 and 4.7 eV, respectively, while $J \sim 0.8$ eV for both configurations. Since the Mn d occupancy in MnPt_3 is about 5.4, we use a value of 5 eV for U in one of the calculations. The calculated Kerr spectra are shown in Fig. 2. As can be seen

FIG. 2. Kerr rotation and ellipticity of MnPt_3 as a function of U obtained in LDA+ U calculations. Experimental curves are the same as in Fig. 1.

in Fig. 2, the disagreement between theory and experiment gets worse than before. A lower value of U (2 eV) improves the result somewhat (Fig. 2) but the agreement with the experiment is still worse than that without U . It can be seen from Figs. 1 and 2 that a small value of U can be chosen to remove the wiggle around 3.5 eV in the Kerr spectra without affecting the rest of the spectra.

In conclusion, the Kerr spectra of MnPt_3 are better described by LDA if LMTO linearization is done about the center of mass of the whole minority Mn d band instead of the occupied part only. The correlation effects beyond LDA introduced by the Hubbard term in the Hamiltonian do not play a significant role in this system. This should also be true for the Mn-based Heussler alloys with similar electronic structure.

Thickness dependence of interfacial magneto-optic effects in Pt/Co multilayers

Xiang Gao,^{a)} Michael J. DeVries, Daniel W. Thompson, and John A. Woollam
*Center for Microelectronic and Optical Materials Research and Department of Electrical Engineering,
 University of Nebraska, Lincoln, Nebraska 68588-0511*

Spectroscopic ellipsometry and magneto-optic Kerr effects are measured on Pt/Co multilayers with a series of Co layer thicknesses from 0.08 to 1 nm. An electromagnetic theory of multilayered structures allows regression analysis fits between acquired data and parameter dependent model analysis. Recently, we determined the single layer Co magneto-optic Voigt parameter and found that it depends on Co layer thickness. In the present work, we report an in-depth study of interfacial magneto-optic effects for a large number of Pt/Co multilayer samples. Kerr rotation and ellipticity were measured over the spectral range from 200 to 1700 nm. Voigt parameters of the magnetic layers for these Pt/Co multilayer samples with different thicknesses were compared, and the Pt-Co interface thicknesses were determined in terms of the material dielectric tensor. © 1998 American Institute of Physics. [S0021-8979(98)46711-2]

I. INTRODUCTION

Metallic multilayers of Pt/Co are very promising magneto-optic (MO) media, especially for the short wavelength range.¹ Our recent studies have shown that the Pt-Co interface regions and the Co rich regions contribute differently to the magneto-optic response, with the Pt-Co interface making the greater contribution.² That is, off-diagonal components of the complex dielectric tensor for the Pt-Co interface are greater in magnitude than those of the Co rich regions. In the study reported in Ref. 2, the thicknesses of the interfaces were assumed to be equal to one atomic layer of Pt, since the growth was at room temperature, resulting in minor atom mixing. Also in our previous work, magneto-optic response studies were limited to the spectral range from 300 to 700 nm.

Due to the larger contribution of the Pt-Co interface to the total MO response, the actual thickness of this interface is very important for the optimum design of Pt/Co multilayer structures. In this article, MO data from a much wider spectral range for two sets of ten Pt/Co multilayer samples are presented. Each set has the same Pt layer thickness and a series of ten magnetic layer thicknesses from very thin to reasonably thick. The magnetic layer (denoted as "mag-opt" layer) includes the Co rich regions as well as the Pt-Co interface regions. The off-diagonal components of the mag-opt layer's dielectric tensor are determined from experiments using electromagnetic magneto-optic theory,^{3,4} in an effort to decide the beginning of the Co rich region and the thickness of Pt-Co interface.

II. THEORY AND EXPERIMENT

An electromagnetic theory (originally proposed by Lissberger and others)⁵ was developed and simplified by McGahan and He for the case of normal incidence polar Kerr

effects.^{3,4} A Jones matrix was used to describe the optical properties of the multilayer structure, as given by

$$\mathbf{J} = \begin{pmatrix} R_x & K_y \\ K_x & R_y \end{pmatrix}. \quad (1)$$

The reflected light beam is related through this Jones matrix to the incident beam by $\mathbf{E}^r = \mathbf{J} \cdot \mathbf{E}^i$, where r and i denote "reflected" and "incident." Kerr rotation and ellipticity θ_k and η_k are defined by $\theta_k = \text{Re}\{K_x/R_x\}$ and $\eta_k = \text{Im}\{K_x/R_x\}$.

For multilayer systems, each of the four elements in the Jones matrix is a function of the thickness and dielectric tensors of the individual layers. The uniaxially symmetric dielectric tensor is given by

$$\tilde{\epsilon} = \begin{pmatrix} \tilde{\epsilon}_{xx} & -\tilde{\epsilon}_{xy} & 0 \\ \tilde{\epsilon}_{xy} & \tilde{\epsilon}_{xx} & 0 \\ 0 & 0 & \tilde{\epsilon}_{zz} \end{pmatrix} \quad (2)$$

and the Voigt parameters are defined as $\tilde{Q} = Q_1 + jQ_2 = -i\tilde{\epsilon}_{xy}/\tilde{\epsilon}_{xx}$. The Q value is a direct indication of the magnitude of the MO response, which increases with increasing Voigt parameter.^{3,4}

To determine the MO responses of the multilayer structures, *in situ* spectroscopic ellipsometry (*in situ* SE) analysis was used to determine the layer thicknesses and diagonal components of the dielectric tensor for each individual layer. In this article these are Pt and mag-opt layers. MO Kerr rotation and ellipticity data were then taken on the samples. The Voigt parameters were determined by regression fitting the MO data to models using Voigt parameters as variables.¹ The layer thicknesses and diagonal dielectric components were obtained from *in situ* SE.

III. EXPERIMENTAL RESULTS AND ANALYSIS

Two series of Pt/Co multilayer structures were deposited using dc magnetron sputtering. *In situ* SE data were taken during the depositions. The thicknesses for the Pt and mag-opt layers in the multilayer structures were determined using

^{a)}Electronic mail: xgao@engr.unl.edu

TABLE I. Thicknesses of samples 1 through 10 (a), and samples 11 through 20 (b) for two series of 50 period multilayers.

(a)										
Sample No. (50 periods)	1	2	3	4	5	6	7	8	9	10
Pt layer thickness (nm)	1.02	1.02	1.02	1.02	1.02	1.02	1.02	1.02	1.02	1.02
Mag-opt layer thickness (nm)	0.08	0.16	0.24	0.32	0.40	0.47	0.55	0.71	0.87	1.03
(b)										
Sample No. (50 periods)	11	12	13	14	15	16	17	18	19	20
Pt layer thickness (nm)	2.04	2.04	2.04	2.04	2.04	2.04	2.04	2.04	2.04	2.04
Mag-opt layer thickness (nm)	0.08	0.16	0.24	0.32	0.40	0.47	0.55	0.71	0.87	1.03

in situ ellipsometric analysis. Meanwhile, the optical constants (diagonal components of the dielectric tensor) of the Pt and mag-opt layer were determined. The thicknesses of the Pt and mag-opt layers of all samples are listed in Table I.

Magneto-optic Kerr rotation and ellipticity data were taken using a modified *ex situ* ellipsometer system.⁶ The spectral ranges of the measurements were from 200 to 1700 nm (0.73 to 6.2 eV). The MO data taken from all samples listed in Table I are shown in Fig. 1. As one can see from Figs. 1(a) and 1(b), the magnitudes of the MO Kerr rotation and ellipticity data increase as the mag-opt layer thickness increases from 0.08 to 0.87 nm, when the Pt layer thickness is fixed at 1.02 nm. There is almost no rotation or ellipticity change between samples 9 and 10. Likewise, for the data in Figs. 1(c) and 1(d), the responses increase as the mag-opt layer thickness increases from 0.08 to 0.71 nm when the Pt layer thickness is fixed at 2.04 nm. The effect saturates for mag-opt layers thicker than 0.71 nm, since the thicker Pt layer prevents the incident light from reaching the bottom mag-opt layers. (Note that there are 50 periods of the multilayers.)

Using the MO analysis described above, the Voigt parameters for the mag-opt layers of each sample were determined by regression fits.⁶ Fits were not unique for the samples with mag-opt layer thicknesses smaller than 0.32 nm, likely because it is too thin to form an actual layer. Fits were excellent and unique for samples with mag-opt layer thicknesses equal to or thicker than 0.32 nm. The spectral range for Voigt parameter fits were limited to 280 to 760 nm, the same as the *in situ* SE spectral range. During the regression fits, equal values of Voigt parameters were assumed for samples with the same mag-opt layer thicknesses but different Pt layer thicknesses.²

In Fig. 2, the Voigt parameters at a wavelength of 350 nm for samples with mag-opt layer thicknesses equal to or larger than 0.32 nm are plotted. We see that, starting from the sample with a 0.40 nm mag-opt layer thickness, the magnitudes of Voigt parameters decrease as the mag-opt layer thicknesses increase. However, the results are almost identical for the sample with 0.32-nm-thick mag-opt layer and 0.40-nm-thick mag-opt layer. As described in the Intro-

FIG. 1. (a) Kerr rotation data for samples 1 to 10 listed in Table I. (b) Kerr ellipticity data for samples 1 to 10 listed in Table I. (c) Kerr rotation data for samples 11 to 20 listed in Table I. (d) Kerr ellipticity data for samples 11 to 20 listed in Table I.

FIG. 2. Voigt parameters Q_1 (a), and Q_2 (b) determined from regression fits for the MO responses in Fig. 1 on samples 4 to 10 and samples 14 to 20.

duction, there are actually two regions, the Co rich region and the Pt-Co interface, in the Pt/Co multilayer structure, and the Voigt parameters for the Pt-Co interface region are larger. Therefore, the pseudo-Voigt parameters (the Voigt parameter determined if there were only one homogeneous region) for both the Co rich region, and the Pt-Co interface should decrease with increase in mag-opt layer thickness. The equal Q values for the sample with 0.32-nm-thick mag-opt layers and 0.40 nm mag-opt layers indicate that the Co rich regions have disappeared. On the other hand, the de-

crease of the Voigt parameters for samples with mag-opt layer thicknesses larger than 0.4 nm indicates that the formation of Co rich regions begins at a thickness of around 0.4 nm (smaller than 0.47 nm). This is very close to the value we assumed in earlier research.²

IV. SUMMARY

Wide spectral range magneto-optic Kerr rotation and ellipticity responses from two series of Pt/Co multilayer structures were measured. An optimal choice between Co layer thicknesses and number of multilayer periods can be made, thus maximizing the magneto-optic Kerr response for practical applications. Finally, by comparing the Voigt parameters of the magnetic layer for samples with mag-opt layer thickness greater than 0.32 nm, a Pt-Co interface thickness of around 0.40 nm was determined.

The optical and polar Kerr magneto-optical properties of a series of Co/Pt/AlN multilayers have been determined in the photon energy range 1.4–4 eV. Observations of the spectral variation of reflectivity are discussed in terms of the optical properties of the constituent materials using multilayer theory. Magneto-optic polar Kerr spectra over the same energy range are also discussed taking into account the modified magnetic properties resulting from undesirable structural changes in the films. © 1998 American Institute of Physics. [S0021-8979(98)44511-0]

INTRODUCTION

The potential of Co/Pt multilayered media for magneto-optic (MO) data storage is widely recognized. However, the magnetic properties of Co/Pt are not ideal. The inclusion of a third material into the system has potential for changing magnetic properties such as the coercivity, anisotropy constant, and Curie temperature. Recently it has been shown¹ that, providing the additional material is a dielectric, the MO potential of the multilayered material remains unchanged, as judged by the figure of merit (FOM),²

$$\text{FOM} = |Q|(\Gamma + \Gamma^{-1}), \quad (1)$$

where Q is the Voigt parameter and $\Gamma (=n/k)$ is the ratio of the real and imaginary parts of the complex refractive index $(n+ik)$. Although Q and Γ may vary on the inclusion of the dielectric component the FOM, in principle, does not. And performance can always be optimized to that of Co/Pt by the use of a carefully designed trilayer structure. We have attempted to fabricate multilayer systems consisting of Co, Pt, and AlN using a multisource, cluster magnetron sputter-deposition system.

We present the results of a series of optical, MO, and magnetic measurements on several multilayers, where the thickness of the AlN layer was varied systematically. The spectral variation of reflectivity is discussed on the basis of the optical properties of the component materials and the MO properties, specifically, the polar Kerr rotation and ellipticity are considered in comparison with the known MO properties of Co, Pt, and Co/Pt. It will be shown, using magnetic and structural data, that changes in MO activity are not due solely to the inclusion of a transparent medium but suffer significant deterioration due to interdiffusion of the AlN into the Pt layers and through the poor stoichiometry of the nitride layer.

EXPERIMENT

All samples were deposited using a multisource, cluster magnetron sputter-deposition system. Sputtering took place

in argon at a partial pressure of 5 mTorr, with a previous base pressure of less than 2×10^{-7} Torr. Both Co and Pt were deposited using dc magnetron sources with deposition rates of 0.06 and 0.11 nm s⁻¹, respectively, onto glass substrates at room temperature.

The AlN was rf sputtered from a stoichiometric target. The deposition rates for Co and Pt were calculated using a TFOS software package in a scanning electron microscope (SEM). The AlN calibrated films could not be accurately measured owing to specimen charging in the SEM, hence a low angle x-ray diffraction was employed. The dielectric layer was multilayered with a thick (2 nm) layer of platinum and the bilayer repeated 20 times. By analyzing the diffraction data the mean bilayer and dielectric thickness were evaluated and hence the associated AlN deposition rate was calculated as 0.78 nm s⁻¹ at an applied power of 150 W.

Two series of films were fabricated on glass substrates with a 5 nm Pt underlayer to induce preferred crystallographic texture in the multilayer that is known to be beneficial for high remanence and anisotropy.³ Series (I) consisted of $10 \times (0.4 \text{ nm Co}/Z \text{ nm AlN}/1 \text{ nm Pt})$ and series (II) was $10 \times (0.4 \text{ nm Co}/0.5 \text{ nm Pt}/Z \text{ nm AlN}/0.5 \text{ nm Pt})$, where Z ranged from 0 to 2 nm.

RESULTS

Using a normal incidence spectroscopic photometer the intensity reflectance (R) was determined for each sample in the two series. The results of these simple measurements are shown in Fig. 1. Generally, the behavior of R for both series is similar and this is to be expected since in the case of $Z = 0.8$ and 1.2 nm the structures contain the same amounts of each material. Moreover, because these are in the form of very thin layers they should have the same effective optical constants.⁴ What is particularly surprising is the magnitude of R , which increases with increasing AlN content and is higher than that for the pure Co/Pt multilayer. The latter is calculated on the basis of the optical constants of Co/Pt multilayered structures.⁵ This result is totally unexpected since the addition of a transparent dielectric like AlN should reduce the reflectivity below that of the pure metallic component. To illustrate what would be expected on the basis of the

^{a)}Electronic mail: ronald.atkinson@qub.ac.uk

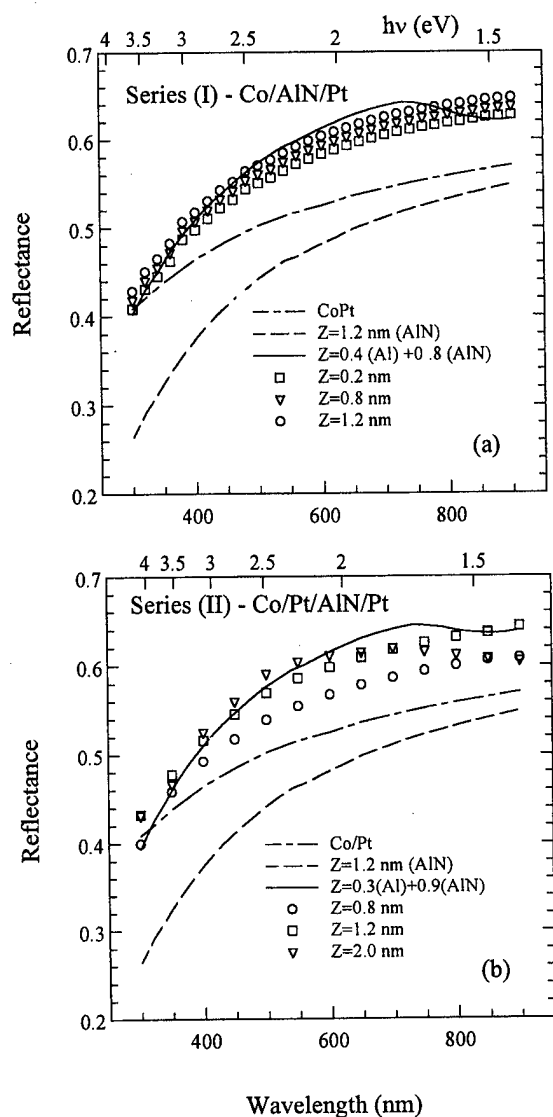

FIG. 1. Normal incidence reflectance for (a) series (I) and (b) series (II). The solid and dashed curves are calculated and the points are measured data.

optical constants of Co, Pt, and AlN we have calculated the reflectivity spectrum for the perfect structures. These are shown as the lower dashed curves in the two cases. In order to explain this anomalous result we considered the possibility that the AlN layer consisted of both AlN and free Al. By varying the proportion of free Al in the sublayers we were able to account for the increased reflectance. To illustrate the improvement we consider the samples with $Z = 1.2$ nm. In Fig. 1(a) with each AlN layer made up from the equivalent of 0.4 nm of Al and 0.8 nm of AlN and in Fig. 1(b), 0.3 nm Al and 0.9 nm AlN there is a much improved agreement with the measured values. Calculations were made using classical electromagnetic theory of multilayers as a first approximation in dealing with this problem. In light of the complex structures involved here and the uncertainties in the stoichiometry and form of the AlN layer the improvement is quite remarkable. Readers may note a reflectance shoulder at long wavelengths in these calculated curves. This is due to the rapidly changing optical constants of Al at a wavelength of 800 nm. In general this is not seen in the

FIG. 2. Perpendicular and parallel hysteresis loops for film series (I).

measured data except for that corresponding to the film with the thickest AlN layer [Fig. 1(b), $Z = 2$ nm] which shows a turning point similar to that seen in the calculated curves. This is consistent with the above arguments, favoring the existence of significant amounts of free Al in the layers.

Figure 2 show the perpendicular and in-plane hysteresis loops for the films in series (II). Similar loops can be observed for series (I). It is quite clear that the addition of AlN to this system results in a gradual decrease in perpendicular anisotropy and coercivity with the result that there is a pronounced shearing of the loop. In the case of $Z = 2$ nm any residual anisotropy has been overcome by the demagnetizing fields and the easy axis of the sample lies in the plane of the film. Since it is known that the perpendicular anisotropy in Co/Pt multilayers arises due to interactions at the interfaces between Co and Pt, the loss of anisotropy is not surprising for the films of series (I) where the AlN layer separates the Co and Pt. However, since the AlN layer in series (II) is located between two Pt layers, one might expect the anisotropy to remain. Evidently this is not the case.

The polar Kerr rotation and ellipticity were obtained with the films in a magnetically saturated state, at normal incidence, using a rotating analyzer Kerr polarimeter with a precision of $\pm 0.005^\circ$. The results are shown in Fig. 3 for both series of films, (I) and (II). For comparison the curves corresponding to Co/Pt are also shown.

FIG. 3. Measured complex Kerr rotation and ellipticity. Dashed lines—series (I); solid lines—series (II).

It should be noted that the dominant component of the MO activity is associated with the Kerr rotation rather than with the ellipticity that is approximately a factor of 4 smaller over the whole spectral range. It is clear that as the amount of AlN increases the MO activity decreases. This is to be expected, even under ideal conditions since we are diluting the system with a nonmagnetic component. However, in this case the decrease is accelerated. On the basis of multilayer calculations, the variations seen in Fig. 3 cannot be reproduced in detail, although some aspects of the curve shapes can be generated. The reasons for the deteriorating performance of both sets of films are complex and will be discussed below.

One can observe that the Kerr rotations produced by series (I) are significantly lower than those in series (II) for the same AlN thickness. The reason for this is that in the former the dielectric layer directly interrupts the Co–Pt interface. This has the effect of reducing the perpendicular

interfacial anisotropy. This is clearly indicated by the magnetic properties of the films. In addition, since the polarization of the Pt layers has its origins at this interface,⁶ this too is reduced and the magneto-optic contribution of the Pt component is lost. The result is a massive decrease in magneto-optic activity. In the case of the second series the AlN layer is situated between the two Pt layers each of which forms an interface with Co. Nevertheless the MO activity is less what might be expected. This may be caused by the existence of the free Al component referred to in the discussion of the optical properties. The intimate mixing of an optically absorbing nonmagnetic element to any magneto-optic structure like this will cause a decrease in magneto-optic effects. In addition, it is clear that perpendicular anisotropy is also being lost. The implication is that, despite the fact that the AlN layer is deposited between Pt, there is a disruption of the Co/Pt interfaces, resulting in lost anisotropy and hence reduced polarization of the Pt and even perhaps lost magnetization within the Co layers. Some evidence for interdiffusion of the elements of these structures caused by the presence of the AlN has been reported in an earlier paper.⁷ Clearly, if this interfacial mixing occurs in the case of series (II), then it is also likely to be present in series (I), and with even greater effect.

SUMMARY

Two series of Co–AlN–Pt multilayer samples were fabricated by magnetron sputtering in an attempt to demonstrate that MO potential is not a function of the thickness of the dielectric layer. However, the magnetic perpendicular anisotropy normally associated with Co/Pt multilayers is gradually reduced with increasing AlN content whether the AlN is located between the Co and Pt or between two Pt layers. Measurements of optical reflectivity suggest that free Al is present in the structures and may indicate that nitrogen diffuses through the structure gradually disrupting the multilayer structure. This causes a severe reduction in MO activity through the loss of polarization of the Pt and perhaps lowering the magnetization of the Co layers. The deteriorating film properties make further meaningful analysis unprofitable.

Effect of Pt in TbFeCo on magnetic and magneto-optical properties

Y. Itoh,^{a)} W. P. Van Drent, and T. Suzuki

Information Storage Materials Laboratory, Toyota Technological Institute, 2-12-1, Hisakata, Tempaku-ku, Nagoya 468, Japan

The effect of Pt additives in TbFeCo(Pt)/Pt multilayers on magnetic properties and magneto-optical Kerr effect is investigated. The perpendicular magnetic anisotropy K_u of the multilayer becomes larger ($\sim 2 \times 10^6$ erg/cm³) than that of the TbFeCo(Pt) single layer. Pt layers are found to contribute significantly to the polar Kerr spectra at ultraviolet photon energies beyond 4 eV. The largest enhancement in the Kerr rotation θ_K is found at about 5 eV. The Kerr rotation θ_K and ellipticity η_K are enhanced with increasing Pt layer-thickness t_{Pt} , and become saturated at $t_{Pt} = 12$ Å. This result implies that Pt atoms up to about 6 Å from the interfaces are contributing to the Kerr activity.

I. INTRODUCTION

Future high density optical recording technology requires novel materials with high polar Kerr activities at short wavelengths. TbFeCo amorphous films currently used exhibit a substantial reduction in Kerr activity with decreasing wavelength¹ and therefore, it is desirable to enhance it by adding some elements. Pt is known to be effective in enhancing the magneto-optical Kerr effect at short wavelengths, as demonstrated in Co/Pt multilayers.²⁻⁴ Awano *et al.* indicated that the Kerr rotation of the rare-earth transition-metal (RE-TM)/Pt multilayer was larger than that of the RE-TM single layer at λ down to 300 nm.⁵

In order to clarify the effect of Pt in the TbFeCo/Pt multilayer, a systematic study of the dependence of magnetic and magneto-optical properties on Pt layer thickness has been made. The magneto-optical Kerr effect of the multilayers was examined in ultraviolet photon energies (~ 6.8 eV) for the first time.

II. EXPERIMENT

Multilayered films of TbFeCo(Pt)/Pt were fabricated by sputter deposition in Ar atmosphere. The base pressure of the sputtering chamber is better than 5×10^{-8} Torr. Ar gas pressure during the deposition is 5 mTorr. The samples were fabricated by depositing TbFeCo and Pt onto glass substrates. The deposition rate for both was 0.5–1 Å/s. The Pt mixture in the TbFeCo layer was detected at a level of less than 1 at % by electron probe microanalyzer (EPMA), although the attempt was made so that the vapor streams were interrupted alternately for programmed times with shutters. The composition of the TbFeCo(Pt) layer exhibited to be TM rich. The thicknesses of TbFeCo ($=t_{TbFeCo}$) and Pt layers ($=t_{Pt}$) were varied from 10 to 50 Å and 0 to 24 Å, respectively. The total thickness of the multilayer was designed for 250 and 500 Å. Measurements of magnetic properties were carried out using a vibrating sample magnetometer (VSM), an alternating gradient field magnetometer (AGFM), and a torque magnetometer. The magneto-optical Kerr effect and

optical constants were measured using a Kerr spectroscopy in a photon energy from 1.4 to 6.8 eV ($\lambda = 182$ –886 nm). Details of the setup are described elsewhere.⁶

III. RESULTS AND DISCUSSION

A. Magnetic property

Samples with a total thickness of the multilayer between 450 and 500 Å were prepared by sputter deposition. A 30 Å thick Pt layer was used as an overcoat on each film for protection. Hysteresis loops measured for these samples by AGFM are shown in Fig. 1. This figure indicates the dependence of hysteresis loops on Pt layer-thickness t_{Pt} for a constant TbFeCo(Pt) layer-thickness t_{TbFeCo} of 50 Å. The TbFeCo(Pt) single layer of the same total thickness, i.e., $t_{Pt} = 0$, is also given in Fig. 1 for comparison. For all the Pt thicknesses under consideration, the hysteresis loops maintain the perfect squareness, though a small kink is observed at very small fields. As t_{Pt} increases, the saturation magnetization M_s also increases, and the coercivity H_c decreases except for the case of $t_{Pt} = 1$ Å.

Figure 2 shows the coercivity H_c as a function of t_{Pt} for various t_{TbFeCo} . At $t_{Pt} = 0.5$ Å, H_c increases drastically for the cases of $t_{TbFeCo} = 30$ and 50 Å, and then decreases monotonously. The increase in H_c is not due to a compensation point because the polarity of the Kerr effect does not change on both sides. The Barkhausen volume V_B was measured through the apparent coercivity as a function of the sweeping speed for the magnetization curves.⁷ It was found that the V_B values are indeed the smallest for this t_{Pt} region. Therefore, the rapid increase of H_c is due to an increase in pinning sites over the interfacial regions.

Figure 3 shows the dependence of K_u on t_{Pt} for various t_{TbFeCo} . K_u is the intrinsic perpendicular magnetic anisotropy constant, defined as $K_0 + 2\pi M_s^2$, where K_0 is the torque amplitude extrapolated to an infinite field strength. As seen in this figure, K_u increases with t_{Pt} for all the cases. K_u becomes significantly larger for $t_{Pt} > 3$ Å at $t_{TbFeCo} = 50$ Å, and for $t_{Pt} > 1$ Å at $t_{TbFeCo} = 30$ Å. For the case of $t_{TbFeCo} = 10$ Å, it seems that $t_{Pt} < 1$ Å is enough to increase K_u . The small K_u at $t_{Pt} = 0$ is due to the Pt dilution (~ 1 at %) in the TbFeCo. Katayama *et al.* also reported that the Pt addition

^{a)}Electronic mail: d2syito@ypcfs1.toyota-ti.ac.jp

FIG. 1. Hysteresis loops for TbFeCo(Pt)/Pt multilayers. (a) TbFeCo(Pt) single layer, (b) $9 \times [50 \text{ Å TbFeCo(Pt)/1 Å Pt}]$, (c) $9 \times [50 \text{ Å TbFeCo(Pt)/3 Å Pt}]$, (d) $8 \times [50 \text{ Å TbFeCo(Pt)/6 Å Pt}]$, and (e) $8 \times [50 \text{ Å TbFeCo(Pt)/12 Å Pt}]$.

decreases K_u in amorphous RE-TM films.⁸ From this point of view, the multilayered film has an advantage. The critical point, at which each K_u becomes saturated, seems to be related to the $t_{\text{Pt}}/t_{\text{TbFeCo}}$ ratio.

FIG. 2. Coercivity H_c as a function of t_{Pt} for various t_{TbFeCo} .

FIG. 3. Dependence of K_u on t_{Pt} for various t_{TbFeCo} .

FIG. 4. The Kerr rotation angle (a) ellipticity (b) and $R(\theta_k^2 + \eta_k^2)^{1/2}$ (c) of $30 \text{ Å TbFeCo(Pt)/}t_{\text{Pt}}$ multilayers ($t_{\text{Pt}} = 0\text{--}24 \text{ Å}$) as a function of photon energy.

B. Magneto-optical property

Very thin multilayers, of which a total thickness is about 250 Å, were deposited on a 750 Å thick Pt reflector for this measurement. Neither any overcoat nor enhancing layer was deposited on each multilayer. This structure is suitable for obtaining an intrinsic Kerr spectrum of a multilayer without optical interference effects. The magneto-optical Kerr effect just after the deposition was measured.

Figure 4 shows the photon energy dependence of (a) the Kerr rotation angle θ_K , (b) ellipticity η_K , and (c) Kerr signal $S = R(\theta_K^2 + \eta_K^2)^{1/2}$, where R is the reflectivity calculated by measured optical constants, for various Pt layer-thicknesses t_{Pt} and a 30 Å thick TbFeCo(Pt). As seen in this figure, the absolute value of Kerr rotation increases with increasing Pt layer thickness. This implies the enhancement is due to Pt. The enhancement becomes evident at ultraviolet photon energies beyond 4 eV. The peak position of the θ_K enhancement is about 5 eV. Pt layers have a negative effect for the enhancement on η_K at photon energies <5 eV and a positive effect at >5 eV. It is found that the enhancements of both θ_K and η_K become saturated at $t_{Pt} = 12$ Å. This result is of interest since one can estimate a range from the interface to be 6 Å (half the t_{Pt}), under which Pt atoms are likely being polarized, giving rise to the higher Kerr activity. As a result, the difference (enhancement) of θ_K value at 5 eV reaches 0.23°. The Kerr signal in Fig. 4(c) reflects those results, and it becomes larger to 2.5 times at 5 eV.

IV. SUMMARY

A systematic experimental study to examine the effect of Pt on both magnetic and magneto-optical properties is presented. The large H_c (>20 kOe) is obtained at about t_{Pt}

= 0.5 Å for 50 Å thick TbFeCo(Pt)/Pt multilayers. K_u initially increases with t_{Pt} , and then remains constant ($\sim 2 \times 10^6$ erg/cm³) for thicker values. From this point of view, the multilayered film has an advantage for enhancing H_c and K_u . The effect of the addition of Pt layers on the Kerr spectra becomes evident at ultraviolet photon energies beyond 4 eV. The largest enhancement in θ_K takes place at around 5 eV. The θ_K is enhanced with increasing t_{Pt} . In the case of $t_{TbFeCo} = 30$ Å multilayers, the enhancements of both the Kerr rotation θ_K and ellipticity η_K become saturated at about $t_{Pt} = 12$ Å. This result implies that Pt atoms up to about 6 Å from the interfaces are contributing to the Kerr activity.

Magneto-optical properties of Sc-substituted erbium-iron-garnet single crystals

J. Ostoréro^{a)}

CNRS, UPR 209, 92195 Meudon Cedex, France

M. Guillot

CNRS-LCMI/MPI, 38042 Grenoble Cedex, France

The magneto-optical properties of $\text{Er}_3\text{Fe}_{5-z}\text{Sc}_z\text{O}_{12}$ ($z=0.10$ and 0.30) single crystals are presented and compared to those of pure ErIG. Faraday rotation (FR) measurements at 1152 nm wavelength were performed in the 6–600 K temperature range under a magnetic field of up to 20 kOe applied parallel to the [100] and [111] crystallographic axes of the crystals. The compensation temperature T_{comp} is shifted from 80 ($z=0$) to 51 K ($z=0.30$). Below T_{comp} , the diamagnetic Sc^{3+} substitution in the octahedral Fe^{3+} sublattice also has a strong influence on FR anisotropy: both spontaneous FR Φ_s and FR susceptibility $\chi_F = d\Phi/dH$ show that the “easy” FR axis changes from [111] in ErIG ($z=0$) to [100] for $z=0.30$. The FR isotherms ($z=0.30$) for the [111] direction show a nonlinear behavior in the 20 K– T_{comp} temperature region. © 1998 American Institute of Physics. [S0021-8979(98)44611-5]

I. INTRODUCTION

In ferrimagnetic rare earth-iron-garnet, formula of $\text{RE}_3\text{Fe}_5\text{O}_{12}$ (REIG), the magnetic ions are distributed over three crystallographic sites: octahedral site $16a[\text{Fe}^{3+}]$, tetrahedral site $24d(\text{Fe}^{3+})$, and dodecahedral site $24c\{\text{RE}^{3+}\}$.¹ The $\text{Fe}[a]$ – $\text{Fe}(d)$ superexchange interactions determine the Néel temperature ($T_N=560$ K) for all REIGs. In heavier rare earth garnets, the influence of the rare earth is manifested by a compensation temperature T_{comp} at which the bulk magnetization vanishes. In pure ErIG, T_{comp} is equal to 80 K.²

At low temperature ($T < T_{\text{comp}}$), ErIG presents anisotropic physical properties which were studied using different techniques, particularly magnetization,² neutron diffraction,³ and magneto-optical (MO) properties.^{4–6} These different results, sometimes confusing or contradictory due in part to the sensitivity of the anisotropy properties to magnetic and thermal sample history,³ enable one to distinguish between the magnetic and MO Faraday rotation (FR) anisotropy properties performed on the same monocrystalline samples.

MO results indicate that [111] is the “easy” axis of ErIG corresponding to the greatest FR absolute values.^{6,7} Concerning the magnetic anisotropy, the spontaneous magnetic properties show that a spin reorientation occurs at ~50 K (Ref. 2) and that the easy magnetic axis is [100] at low temperature. Nevertheless, the spontaneous magnetization along [100] and [111] is only slightly different as was shown for rare earth-iron-garnets where the rare earth (here Er^{3+}) is a Kramers ion.⁸ Moreover, below ~75 K in ErIG, in the rare earth sublattice, when both crystal field effects and exchange Fe^{3+} – RE^{3+} interaction anisotropies become of the same order of magnitude, the ferrimagnetic order is destroyed and an onset of a noncollinear ordering takes place in the $\{c\}$ sublattice as shown by neutron diffraction

experiments.^{2,3} Finally, an anomaly in the magnetic anisotropy near 6 K has been observed recently⁹ which was related to the splitting of the lowest Kramers doublet of Er^{3+} by the anisotropic exchange interaction with the iron sublattices.

An effective mean of modifying the exchange interaction between RE and Fe sublattices is to substitute Fe^{3+} ions by diamagnetic ones in $\text{RE}_3\text{Fe}_{5-z}\text{M}_z\text{O}_{12}$ garnets ($\text{M}=\text{Al}, \text{Ga}, \text{Sc}$). In contrast to Al^{3+} and Ga^{3+} ions which substitute to Fe^{3+} ions on both tetrahedral (d) and octahedral [a] sites with a large tetrahedral preference, Sc^{3+} ions substitute almost exclusively to Fe^{3+} on octahedral sites¹⁰ and have a stronger influence on the RE–Fe exchange interaction than Al^{3+} or Ga^{3+} .^{10,11} However, the influence of the diamagnetic scandium substitution on the magnetic and MO properties of garnets has been limited mainly to yttrium-iron-garnet compounds $\text{Y}_3\text{Fe}_{5-z}\text{Sc}_z\text{O}_{12}$.¹⁰ We present here for the first time, to the best of our knowledge, the MO properties of $\text{Er}_3\text{Fe}_{5-z}\text{Sc}_z\text{O}_{12}$ ($z=0.10$ and 0.30) single crystals and in particular Faraday rotation at 1152 nm wavelength. In order to emphasize the influence of Sc substitution on the MO properties of ErIG, FR measurements were performed for the same experimental conditions as a function of temperature and magnetic field oriented along the principal crystallographic axes [100] and [111] and compared to previous results on pure ErIG.^{4–6} The magnetic properties of these compounds will be described in a forthcoming paper.

Using the method of flux growth under 10 bar of oxygen pressure, single crystals of $\text{Er}_3\text{Fe}_{5-z}\text{Sc}_z\text{O}_{12}$ with $z=0.10$ and 0.30 were synthesized. The scandium content was determined by electron microprobe analysis to within $\pm 2\%$ accuracy. X-ray diffraction measurements were in agreement with the garnet Ia $3d$ structure, the lattice parameters being 1.2347, 1.2358, and 1.2379 nm for $z=0, 0.10$, and 0.30 , respectively. Polished platelets ~0.4 mm thick oriented perpendicular to the [111] and [100] axes were obtained from the same “as grown” crystal to avoid the slight Sc concen-

FIG. 1. FR isotherms of ErIG:Sc ($z=0.10$) at 1152 nm for $T < T_{\text{comp}}$ ($T_{\text{comp}} = 71$ K) and H parallel to [111]. The saturation field H_{sat} is indicated by the dashed curve. When H is parallel to [100], $H_{\text{sat}} \leq 4$ kOe in the whole temperature range.

tration difference which can occur between different crystals of the same batch. FR measurements Φ were performed at temperatures between 6 and 600 K under a magnetic field of up to 20 kOe applied parallel to the [111] or [100] direction at a wavelength of 1152 nm using a modulation technique. This wavelength is in the transparency window of the garnet—the nearest Er absorption lines are located at about 6500 cm^{-1} ($^4I_{15/2} \rightarrow ^4I_{13/2}$ transition) and at about 10000 cm^{-1} ($^4I_{15/2} \rightarrow ^4I_{11/2}$ transition)¹²—and the MO properties presented in this article are mainly dispersive. The experimental accuracy is estimated to $\pm 2\%$ for Φ . It is to be noted that the samples are cooled to the lowest temperature in the absence of a magnetic field prior to FR measurements.

II. RESULTS AND DISCUSSION

FR isotherms $\Phi(H)$ are plotted in Fig. 1 ($z=0.10$) and Fig. 2 ($z=0.30$). They present a linear part when $H \geq H_{\text{sat}}$. A least-squares fit of these linear isotherms using $\Phi = \Phi_s + \chi_F H$ gives the spontaneous FR $\Phi_s(T, z)$ and FR susceptibility $\chi_F(T, z)$. For all Sc concentrations, two different temperature regions are evidenced according to T_{comp} of the samples. In the vicinity of T_{comp} , FR isotherms are no longer linear and the FR changes its sign within $T_{\text{comp}} \pm 2$ K, keeping the same absolute values. The values of T_{comp} are 71 and 51 K for $z=0.10$ and 0.30 , respectively.

Below T_{comp} , H_{sat} is strongly dependent on the Sc concentration, orientation, and temperature of the sample and a strong FR anisotropy is observed. When $z=0.10$ and H parallel to [111] (Fig. 1), H_{sat} is a complex function of temperature and presents a maximum $H_{\text{sat}} = 12$ kOe in the 15–25 K temperature region. This is in contrast with the FR isotherms for $z=0.10$ and H parallel to [100]: in this case, H_{sat} is at most 4 kOe at 6 K. Concerning the linear part of the isotherms, they are identical within experimental accuracy for

FIG. 2. FR isotherms of ErIG:Sc ($z=0.30$) at 1152 nm. To avoid confusion, the Φ axis is broken according to different isotherms. Closed symbols: H parallel to [100]. Open symbols: H parallel to [111].

$z=0.10$ and H parallel to [100] and [111] giving the same FR spontaneous values, Φ_s , and FR susceptibilities, χ_F . When $z=0.30$, the anisotropy below T_{comp} is much stronger (Fig. 2). When H is parallel to [100], H_{sat} is at most 4 kOe in the whole temperature range. On the contrary, when H is

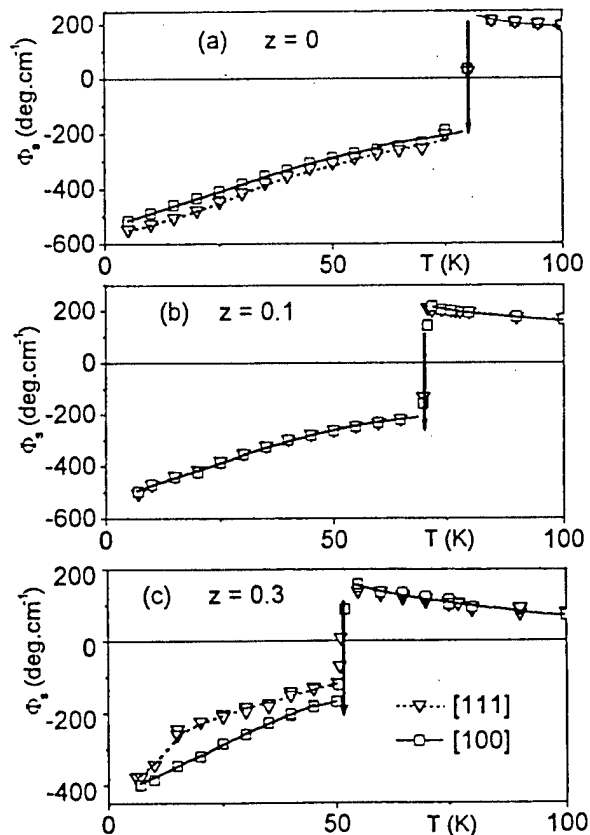

FIG. 3. Temperature variation of the spontaneous FR $\Phi_s(T)$ for (a) $z=0$, (b) $z=0.10$, (c) $z=0.30$ when H is parallel to [100] (\square) and when H is parallel to [111] (∇). The arrows indicate T_{comp} .

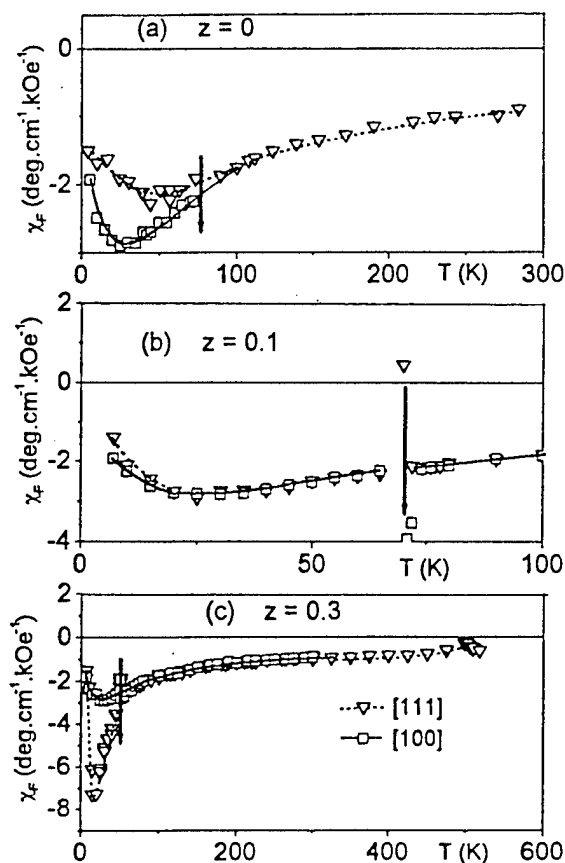

FIG. 4. Temperature variation of the FR susceptibility $\chi_F(T)$ for (a) $z=0$, (b) $z=0.10$, (c) $z=0.30$ when H is parallel to [100] (\square) and when H is parallel to [111] (∇). The arrows indicate T_{comp} .

parallel to [111], H_{sat} is strongly temperature dependent and the FRs are nonlinear in the 20 K– T_{comp} temperature zone. When $T > T_{\text{comp}}$ (Fig. 2), the anisotropy of the FR is no longer present and H_{sat} is of the order of 2 kOe for all concentrations and orientations.

The influence of the Sc concentration on the MO properties of the samples is best evidenced by the spontaneous FR $\Phi_s(T)$ presented in Fig. 3 for $z=0$, 0.10, and 0.30. Below T_{comp} , the FR anisotropy is present for $z=0$ and 0.30. The greater spontaneous absolute values are obtained when H parallel is to [111] for $z=0$ and H is parallel to [100] when $z=0.30$. The smallest values of H_{sat} are obtained for [100] and [111] when $z=0.30$ and 0, respectively. This indicates that in the experimental magnetic field range 0–20 kOe, the “easy” axis is shifted from [111] in pure ErIG garnet to [100] in ErIG:Sc with the greatest amount of Sc in the samples studied. This is confirmed by the behavior of the intermediate Sc concentration $z=0.10$. In this case, no FR anisotropy is observed within experimental accuracy. The only observed FR anisotropy concerns the “saturation” magnetic field which differs strongly as stated above.

This behavior is confirmed for the FR susceptibility, $\chi_F(T, z)$ (Fig. 4). In this case, the lowest χ_F values correspond to the easy axis as $|\chi| = |d\Phi/dH|$ is minimal at saturation. The easy axis is well shifted from [111] to [100] when z varies from 0 to 0.30. Note the discontinuity in the vicinity of T_{comp} .

FIG. 5. Temperature variation of the spontaneous FR of $\text{Y}_3\text{Fe}_{5-z}\text{Sc}_z\text{O}_{12}$ ($z=0.30$) for H parallel to [100] and [111].

Within the framework of the one ion model,¹³ the FR of a three sublattice rare earth–iron–garnet is given by

$$\Phi_{\text{ErIG:Sc}} = \Phi_{\text{Er}} \mp \Phi_{\text{YIG:Sc}} = \pm (C_e + C_m) |M_c| \mp \Phi_{\text{YIG:Sc}}, \quad (1)$$

where $\Phi_{\text{Er}}(\lambda, T)$ is the Er^{3+} contribution to the spontaneous FR and the contributions from the Fe^{3+} [a] and (d) sublattices are represented experimentally by the FR at the same wavelength of the corresponding YIG garnet of the same composition.¹¹ Upper (lower) signs are valid for $T < T_{\text{comp}}$ ($T > T_{\text{comp}}$). $C_{e,m}(\lambda)$ are the respective MO electric “ e ” and magnetic “ m ” dipole coefficients of the $\{c\}$ sublattices with magnetizations $M_c(T)$.

We plotted in Fig. 5 the spontaneous FR of $\text{Y}_3\text{Fe}_{5-z}\text{Sc}_z\text{O}_{12}$ single crystals for $z=0.30$ with H parallel to [111] and [100]. Within experimental accuracy, no significant FR anisotropy is observed (maximum difference 4% at 6 K and less when T increases). For the magnetic anisotropy of YIG:Sc, the scandium substitution leads only to a variation of the K1 anisotropy constant smaller than 30% at 4.2 K when $z=0.30$.¹⁴ Therefore, the FR anisotropy observed in the ErIG:Sc single crystals is related to the Er sublattice.²

A. Kumar and H. Bakhru

Department of Physics, State University of New York at Albany, Albany, New York 12222

Epitaxial liftoff has been used for achieving heterogeneous integration of many III-V and elemental semiconductor systems. However, it has been heretofore impossible to integrate devices of many other important material systems. A good example of this problem has been the integration of single-crystal transition metal oxides on semiconductor platforms, a system needed for on-chip thin film optical isolators. We report here an implementation of epitaxial liftoff in magnetic garnets. Deep ion implantation is used to create a buried sacrificial layer in single-crystal yttrium iron garnet (YIG) and bismuth-substituted YIG (Bi-YIG) epitaxial layers grown on gadolinium gallium garnet (GGG). The damage generated by the implantation induces a large etch selectivity between the sacrificial layer and the rest of the garnet. Ten-micron-thick films have been lifted off from the original GGG substrates by etching in phosphoric acid. Millimeter-size pieces of excellent quality have been transferred to the silicon and gallium arsenide substrates. Study of the magnetic domain structure in the detached epilayers by Faraday contrast shows no changes in film anisotropy. Optical insertion loss measurements are also presented. © 1998 American Institute of Physics. [S0021-8979(98)31611-4]

The integration of magnetic garnet waveguides into silicon, gallium arsenide or indium-phosphite-based photonic integrated circuits (PICs) is of considerable technological importance. Optical isolators and circulators, which are essential components in the laser-source emitter end of the circuit, rely on the nonreciprocal properties of magnetic garnets for their operation. Bismuth-substituted yttrium iron garnet (Bi-YIG) and other rare-earth magnetic garnet films, used in the fabrication of these devices, are normally grown by liquid-phase or radio frequency sputter epitaxy on gadolinium gallium garnet (GGG) substrates. As a result it would be useful to develop viable techniques for on-chip integration of isolator materials. Despite several attempts, epitaxial growth of single-crystal magnetic garnets has not been realized on semiconductor substrates. As a result the integration of magneto-optic isolators and circulators into photonic circuits must rely on hybrid mounting techniques or wafer bonding and epitaxial liftoff.

The technology for epitaxial liftoff has been developed mostly in III-V semiconductors. It makes use of the large differential etch rate between a buried sacrificial layer and the epitaxial structure of interest to detach the latter from the substrate on which it has been grown. The technique was pioneered by Yablonovitch *et al.*¹ by relying on the high etch selectivity of AlAs over $\text{Al}_x\text{Ga}_{1-x}\text{As}$ in hydrofluoric acid. Subsequent work has demonstrated the liftoff of epitaxially grown layers in other III-V materials and the bonding of such layers on a variety of substrates. More recently Hunn *et al.*² have also demonstrated the separation of thin single-crystal diamond films from bulk diamond.

The work that we report here studies the technique of crystal ion slicing (CIS) for liftoff of a thin epitaxial layer. In

this technique buried sacrificial layers are formed in magnetic garnets, allowing the subsequent liftoff and bonding of $\sim 10\text{-}\mu\text{m}$ -thick films to semiconductor substrates. Deep ion implantation is used to generate a damage layer several microns beneath the sample surface. Since residual ion damage can, in principle, affect the top surface, techniques to minimize this damage should be examined in order to produce high quality films. For example, we have found that rapid thermal annealing eliminates this residual damage without jeopardizing the epitaxial liftoff process. Films of excellent quality are detached from the original substrate and van der Waals bonded to silicon and gallium arsenide. Faraday contrast examination of the magnetic domains in the samples shows that there is no noticeable change in the coercivity of the garnet as a result of the epitaxial liftoff process.

The samples used in this study are $10\text{-}\mu\text{m}$ and $95\text{-}\mu\text{m}$ -thick single-crystal films of YIG grown by liquid-phase epitaxy on a (111)-oriented GGG substrate. These epitaxial films have a formula unit of $\text{Y}_3\text{Fe}_5\text{O}_{12}$, with small amounts of lanthanum to improve lattice matching to the GGG substrate. Three- μm -thick Bi-YIG epitaxial films on GGG are also used to study the effect of ion implantation below the epilayer/substrate interface. The uniaxial growth anisotropy in these samples, typical of Bi-YIG films, results in the formation of magnetic domains with the magnetization directed normal to the sample surface. These domains can be easily observed via Faraday-contrast microscopy and their response to an applied magnetic field is used here to study the effect of ion implantation and epitaxial liftoff on the magnetic properties of the sample. The bismuth-substituted epilayers have a formula unit of $\text{Bi}_{0.6}\text{Y}_{2.4}\text{Fe}_5\text{O}_{12}$, with trace amounts of gallium.

Singly charged 3.8 MeV helium ions are implanted normal to the surface into the YIG and Bi-YIG epilayers, with-

^{a)}Electronic mail: MIGUEL@CUMSL.CTR.COLUMBIA.EDU

out any masking. The implant dose on all samples is 5×10^{16} ions/cm². The samples are mounted on a specially designed, 2 in. diam water-cooled target holder to ensure that the temperature of the substrate is below 400 °C. As an added precaution the beam current during the implant is kept low ($<0.25 \mu\text{A}/\text{cm}^2$). These precautions are necessary to avoid thermal modification of the optical absorptivity and magnetic anisotropy of the sample during implantation. The uniformity of the implantation is monitored by four Faraday cups outside the target holder.

Helium is chosen as the implantation species because of its light weight, yielding a deeply buried damage layer. Two dominant mechanisms for energy loss determine the implantation profile and the distribution of lattice damage in the crystal.³ The energy loss per unit trajectory length, known as the stopping power, is dominated by electronic scattering at high ionic energies. Energy loss for this process is adequately described by the Lindhard-Scharff-Schiott (LSS) theory,⁴ which predicts a stopping power proportional to $E^{1/2}$. Here E is the energy of the implanted ion along its trajectory. This process generates very little lattice damage.³ At low energies the stopping power is primarily due to Rutherford scattering with the host nuclei, and is inversely proportional to E^2 . This nonlinear dependence ensures that the majority of the ions are deposited in a relatively narrow spatial region of the sample.

Lattice defects are introduced by the transfer of energy to the target nuclei, and therefore form near the end of the ionic trajectories. Transport-of-ions-in-matter⁵ (TRIM) calculations for helium implanted at 3.8 MeV of energy into YIG show that the implantation profile is rather narrow and concentrated approximately $9.3 \mu\text{m}$ below the surface. Calculated profiles for the Bi-YIG samples exhibit an implantation depth of $8.8 \mu\text{m}$. Tests were also performed in the same materials for neon implantation, at the same energies and dosage as indicated above. Crystal ion slicing of the neon-implanted samples was unsuccessful due to the much higher level of near-surface damage generated by the heavier neon ions.

Insertion loss measurements in waveguided transmission were performed on the $3\text{-}\mu\text{m}$ -thick Bi-YIG epitaxial films. These tests compared the transmitted optical power of implanted and unimplanted samples at a wavelength of $1.55 \mu\text{m}$. In these samples the sacrificial layer due to the implantation forms about $6 \mu\text{m}$ below the waveguiding slab, in the GGG substrate. Figure 1 shows the total insertion loss relative to the optical fiber output power used to couple light into the waveguide by end-fire coupling. The data exhibit an excess loss of more than 5 dB in the ion-implanted material throughout the range of waveguide lengths studied. This excess loss is due to residual damage inflicted by the ion bombardment on the Bi-YIG epilayer during the implantation. It can be annealed out by rapid thermal annealing (RTA) without compromising the effectiveness of the epitaxial liftoff, as described below. Samples annealed after implantation exhibit no excess transmission loss relative to the unimplanted material, as shown in Fig. 1.

The samples are etched in commercial 85% dilution orthophosphoric acid, an etchant reported previously for lateral

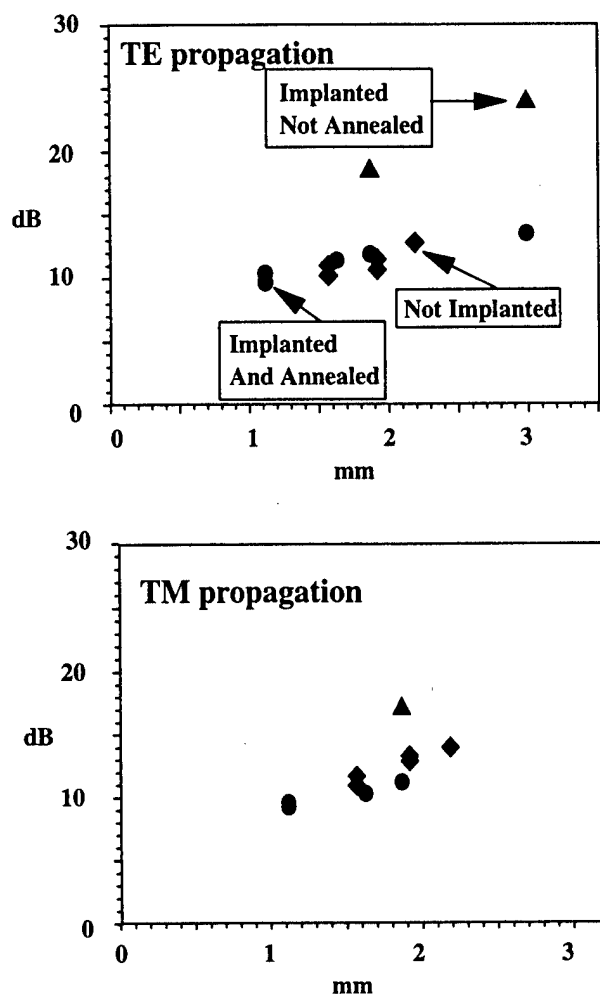

FIG. 1. Insertion loss vs slab waveguide length in Bi-YIG epilayers. The loss is measured relative to the input power. Triangles correspond to implanted material without annealing (RTA), circles to implanted and annealed samples, and rhombi to unimplanted material. The plot shows that there is degradation in insertion loss for ion-implanted waveguides after rapid thermal annealing, relative to the unimplanted material.

patterning of ion-implant waveguides in YIG.⁶ A deep undercut forms after several hours, centered about $9.5 \mu\text{m}$ below the top surface in the YIG and $9 \mu\text{m}$ in the Bi-YIG. The location of the undercut is in good agreement with the calculated implantation profile. Figure 2 is a micrographic side-view of the etched bismuth-substituted sample, showing the liftoff film still attached to its original substrate. Note that the Bi-YIG/GGG interface, located $3 \mu\text{m}$ below the top, appears visually unaffected by the ion implantation and subsequent etching. In particular, it exhibits no selective etching in spite of being traversed by the ionic trajectories during the implantation. The underside of the film, adjacent to the sacrificial layer, is also microscopically smooth.

If unprotected during etching, the top surface of the sample is roughened by exposure to the acid. This roughening is due to residual lattice damage near the top generated by the ion implantation, and correlates with the damage-induced excess loss in the optical measurements described before. Rapid thermal annealing before etching but after implantation repairs this residual damage without compromising the efficiency of the subsequent wet etching of the buried

FIG. 2. Cross section of ion-implanted Bi-YIG showing the undercut as a result of wet etching in phosphoric acid. Note the smooth Bi-YIG/GGG interface $\sim 3 \mu\text{m}$ below the top surface.

layer. Specifically, tests show that a 20 s anneal (RTA) at 700°C in forming gas (5% hydrogen, 95% nitrogen) results in a smooth surface.⁷ The differential etch rate between the sacrificial layer and the rest of the sample is found by comparing the etch rate of the undercut to that of the top surface under the same conditions, and is measured to be in excess of 10^3 .

To fully detach a section of film of a square millimeter area from the substrate, the sample must be in the etchant for about 24 h. But contrary to the case of III-V materials, it is not necessary to rely on the stress created by any protective cover to allow the flow of reaction products away from the etching zone.¹ The films are then van der Waals bonded to silicon or GaAs. Figure 3 shows a YIG film bonded to GaAs. YIG films are quite brittle and must be handled carefully to avoid developing microfractures during the processing. We have been able to produce fracture-free films routinely, but have found that some protective encapsulation is needed to prevent cracks from developing.⁷ Initial tests indicate that this fracture formation is due to stress from bowing of the epilayer during the etching process.

The domain structure in YIG and Bi-YIG films after epitaxial liftoff was studied by Faraday contrast microscopy. The YIG samples used were (111) films with nearly planar anisotropy and some residual cubic anisotropy. Their magnetization was parallel to the [211] directions. The Bi-YIG films had uniaxial anisotropy. No change in anisotropy occurred as a result of the ion implantation and liftoff proce-

FIG. 3. Scanning electron micrograph of a fracture-free YIG film after epitaxial liftoff, onto a GaAs(100) wafer substrate.

dure. This contrasts with the effect of energetic heavy-ion implantation in garnets, where damage-generated changes are found in the domain structure.⁸ Electronic-dominated scattering is responsible for the stopping power in the YIG and Bi-YIG epilayer, causing little damage to the film except in and around the sacrificial layer. Comparison between the saturation magnetic field in the Bi-YIG crystal before and after implantation and liftoff shows no change within experimental uncertainty. Thus no significant degradation in the magnetic response results from damage-generated domain pinning during the crystal ion slicing.

Faraday rotation and magnetic properties of erbium gallium gallate under high magnetic field

M. Guillot,^{a)} T. Schmiedel,^{b)} and You Xu^{c)}

Laboratoire des Champs Magnétiques Intenses, CNRS/MPI 38042 Grenoble, France

Magnetization (M) and Faraday rotation (FR) have been measured in $\text{Er}_3\text{Ga}_5\text{O}_{12}$ single crystals in the 4.2–300 K temperature range under high dc magnetic field up to 300 kOe. Experimental data are reported for H applied parallel to the [111] and [100] directions at 633 and 550 nm wavelength. A strong anisotropy of both magneto-optical and magnetic properties is observed. At low temperature, FR and M are proportional only when the magnetization is weak (small magnetic field). In medium and high magnetic field, complex relationships between M and FR are found. The magnetization cannot account for the whole Faraday rotation anisotropy. These data are discussed taking into account the magnetic and magneto-optical properties of the isomorphous erbium iron garnet ferrite.

I. INTRODUCTION

There has been considerable interest in magneto-optical (MO) properties of magnetic ceramics over the last decades. This attention is particularly due to the promising technological applications of the Faraday rotation (FR) and of the Kerr effect (KE) in optical range devices since magnetization of the material can be read out using MO tools. Although numerous investigations of materials offering a maximum of figure of merit at a specific wavelength of laser diodes were conducted, the theoretical analysis of the MO properties are, however, scarce.^{1,2} Particularly the relationship between magnetization and MO effects was found to be more complex than simple models where the MO properties were supposed to scale proportionally to the magnetization.^{3–5} It should be noted that even inside one unique series of compounds, these studies are very delicate since many parameters like exchange splitting, spin-orbit coupling, lattice parameter cannot vary independently; furthermore they are usually performed at room temperature only where the energy schema are very complicated. One way to avoid this difficult task is to measure magnetic and MO properties on one unique crystal and under high magnetic field and that in a large temperature range.

An evident illustration of the complicated relationship between magnetization and MO properties is given, in the ferrimagnetic iron $\text{Er}_3\text{Fe}_5\text{O}_{12}$ garnet (ErIG), by the contribution to FR of the rare-earth sublattice; the rare-earth contribution vanishes near 75 K even the magnetic moment of the Er^{3+} ion is about of $5 \mu_B$.^{6,7} Recently using quantum theory, we have demonstrated that the rare-earth Fe superexchange interaction (SI) and the crystal field (CF) on the rare earth ion are crucial factors in the calculation of magnetic and MO properties. Furthermore when SI is large, the admixing of different ground term multiplets by the high-order perturbation of SI is important.⁸ Because in the ferrimagnetic garnet structure, SI corresponds to molecular fields in the range

100–300 kOe, we present, in this article, both magnetic and FR measurements in high dc magnetic field up to 300 kOe performed on the isomorphous paramagnetic $\text{Er}_3\text{Ga}_5\text{O}_{12}$ gallate (ErGaG) with special attention paid to the anisotropy of these properties. It is recalled that in ErGaG, the Néel point related to an antiferromagnetic long range ordering is below 1 K, the Er–Er superexchange interaction is negligible and the crystal is paramagnetic at 4.2 K.

II. EXPERIMENT

Faraday rotation (FR) and magnetization (M) measurements were performed on the same single crystals of composition $\text{Er}_3\text{Ga}_5\text{O}_{12}$ grown by the flux method. The FR measurements were realized at the National High Magnetic Field Laboratory (Florida State University Tallahassee USA); the M measurements, at the High Magnetic Field Laboratory (CNRS/MPI Grenoble). After the control of the single crystal quality by x-ray diffraction techniques, the crystal was x-ray oriented, cut, and polished to obtain two disks with respective planes of (111) and (100). The diameters were about 2 mm and the thickness were, respectively, 1.46 and 1.49 mm.

The external magnetic field attained was 300 kOe (FR measurements) and either 262 (at 4.2 K) or 200 kOe (M measurements), H being applied perpendicular to the major plane of each plate. In the first case, the high continuous magnetic field was produced by a 32 mm inner-bore water-cooled resistive magnet connected to a high powerful electrical power (12 MW) supply; in the second one, either a 50 mm inner-bore hybrid or a 50 mm inner-bore water-cooled resistive magnet was used. The magnetic measurements were carried out using the automatic magnetometer described in Ref. 9 leading to an experimental accuracy on M better than $\pm 2\%$.

MO properties like FR and KE have not been investigated much in high magnetic field. However, it was noted that one of the most important experimental difficulties is to separate the contribution of the sample from the contribution of the windows of the cryostat mainly because stray fields are always very large in high field setup.¹⁰ Our optical device will be described in detail in a forthcoming article.¹¹ However we would like to mention that, in contrast to optical

FIG. 1. Magnetization vs magnetic field applied parallel to the [111] and [100] crystallographic directions at 4.2 K in ErGaG.

system of Ref. 10, both the polarizer and the analyzer are located in the near vicinity of the sample in the low temperature chamber. Thin optical fibers were used to conduct the light from the source (lamp plus spectrometer) to the polarizer and from the analyzer to the detector. The polarizer and analyzer were crossed at room temperature in the presence of the sample. It is worth noting that without any sample, the plane of polarization of the emerging light from the analyzer was observed to be insensitive to the simultaneous presence of the high field and of low temperature. Furthermore the crossing of the polarizer and analyzer was observed to be insensitive to the presence of the high field. Finally, the experimental accuracy on FR may be estimated about $\pm 3\%$.

This article is limited to the data obtained at 633 ($15\,797\text{ cm}^{-1}$) and 550 ($18\,182\text{ cm}^{-1}$) nm wavelength. It is recalled that the ErGaG absorption spectrum consists of different sharp lines centered at 6775, 10 415, 12 496, 15 449, 18 525, 19 407, 20 717, 22 371, 22 701, and 24 893 cm^{-1} , respectively. These absorption peaks were attributed to transitions between the ground multiplet $^4I_{15/2}$ and different excited multiplets $^4I_{13/2}$, $^4I_{11/2}$, $^4I_{9/2}$, $^4F_{9/2}$, $^4S_{3/2}$, $^2H_{11/2}$, $^4F_{7/2}$, $^4F_{5/2}$, $^4F_{3/2}$, and $^2G_{9/2}$, respectively.¹²⁻¹⁵

FIG. 3. Faraday rotation vs external field parallel to the [111] and [100] crystallographic directions at 4.2 K in ErGaG; experiments performed at 550 nm wavelength.

III. RESULTS AND DISCUSSION

An example of the magnetic behavior is given by Fig. 1 where the 4.2 K magnetization curves are given. It is noted that in the article, the M values are reported in Bohr magneton per mole where one mole is equal to $2(\text{Er}_3\text{Ga}_5\text{O}_{12})$ and that because there exist six magnetically inequivalent Er sites in the cubic crystallographic unit cell described by the $Ia\bar{3}d$ space group. The experimental data shown evidence of the following properties: (i) in H below about 25 kOe no anisotropy of the magnetization exists within our experimental accuracy ($\pm 2\%$); (ii) above 25 kOe, the field-induced anisotropy is observed between 4.2 and 50 K although at this last temperature, this anisotropy is becoming very weak; (iii) on each isothermal $M(H)$ curve, this anisotropic character is found to be increasing with H . But, the most important feature is the existence of a cross-over field H_{co} about 80 kOe; when $H > H_{co}$, the [100] magnetization is larger than the [111] one. It is clear that no saturation magnetization is observed and it is not possible to conclude unambiguously that [100] is, in the gallate, the easy direction of magnetization as it is in ErIG.¹⁶ However, because along the [100] direction, the relative change of M between 200 and 260 kOe is less than 12%, we deduce that, in this field region, the magnetic moment per Er^{3+} ion is about $7\mu_B$. Following this determination, two comments can be made: first, our value is in good agreement with the rare earth magnetic moment de-

FIG. 4. Faraday rotation susceptibility vs temperature in ErGaG at 633 nm wavelength. (insert: reciprocal FR susceptibility).

FIG. 5. Ratio of the Faraday rotation measured at 633 nm wavelength to the magnetization as a function of the applied field at 4.2 K for ErGaG.

duced in ErIG from direct magnetization measurements¹⁶ and from neutron diffraction study,^{17,18} second, it is confirmed that SI in the ferrite corresponds to external field in the 200–260 kOe range. Furthermore our data show unambiguously the strong quenching of the orbital moment by crystal field (CF) since, even at 4.2 K, the Er^{3+} magnetic moment remains less than the free-ion value corresponding to the ground multiplet $^4I_{15/2}$.

The high field variations of the FR are reported in Figs. 2 and 3 for H parallel to [111] and [100] at 4.2 K. The following remarks must be advanced: (i) the magnitudes of FR are very different for the two wavelengths; (ii) at 633 nm wavelength, a strong anisotropy of FR is evidenced whatever the field strength with the strongest FR observed above 150 kOe along [100]; note the MO cross-over field differs strongly from that found on the $M(H)$ curves (Fig. 1); (iii) at 550 nm wavelength, the FR anisotropy decreases rapidly above 200 kOe; below this field, the highest FR value corresponds to the [111] direction.

Because in low applied field, the FR is linear versus H the FR susceptibility (Verdet constant V) can be deduced; as expected a strong decrease of V with increase in temperature is obtained (Fig. 4). It is worthy to note that the anisotropy of V is present up to 25 K although no magnetic anisotropy was observed in low applied field as mentioned above. As shown in the inset of the Fig. 4, the reciprocal Verdet constant does not present a linear temperature dependence as found in some rare earth trifluorides.¹⁹

The comparison between the high magnetic dependencies of FR and M is illustrated by their ratio plotted in the Figs. 5 and 6 at 4.2 K. A strong anisotropy of this ratio is immediately remarked and it is clear that the relationship between the FR and M is complex. However for the two wavelengths, the ratio FR/ M is found to be field independent above 100 kOe at least for the [100] direction within an experimental accuracy estimated to be 5%. This conclusion may be considered as an experimental confirmation of the model proposed many years ago by Crossley *et al.*²⁰ where in the ferrimagnetic garnets, the contribution to FR of each sublattice is proportional to the sublattice magnetization.

Although MO effects in the visible region are mainly due to intraionic electric dipole transitions between the $4f^n$

FIG. 6. Ratio of the Faraday rotation measured at 550 nm wavelength to the magnetization as a function of the applied field at 4.2 K for ErGaG.

and $4f^{n-1} 5d$ configurations, the strong difference between the data obtained at 633 and at 550 nm wavelength illustrates how the crystal field (CF) is the fundamental perturbation on the electronic states. The choice of the CF parameters is a crucial problem and only values obtained by Nekvasil *et al.*²¹ in SmIG and then corrected by the ratio of the radii of the rare earth ions allow a reasonable interpretation of the data in some light rare earth garnets (see Ref. 8 and references therein).

A reexamination of the magneto-optical (MO) spectra of $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$, MgFe_2O_4 , NiFe_2O_4 , and CoFe_2O_4 is presented. Thus far the MO spectra of these compounds have been explained by either orbital promotion processes, oxygen to iron charge transfer transitions or crystal field transitions and, in the case of CoFe_2O_4 , a single intervalence charge transfer (IVCT) transition. For $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$ and MgFe_2O_4 , the major transitions in the MO-Kerr spectra between 0.5 and 5.0 eV are assigned to intersublattice charge transfer (ISCT) transitions. The MO-Kerr spectrum of NiFe_2O_4 is more complex as in this case both Fe^{3+} and Ni^{2+} contribute to the spectrum. In NiFe_2O_4 an additional IVCT transition is observed at 2.9 eV. The complex MO spectrum of CoFe_2O_4 could be resolved using the dielectric tensors of $\text{Co}^{2+}\text{Al}_x^{3+}\text{Fe}_{2-x}^{3+}\text{O}_4$ ($x=0, 0.1, 0.6$, and 1) and rigorously fitting both the diagonal and the off-diagonal elements of the dielectric tensor with one set of transitions which was consistent for all degrees of Al^{3+} substitution. Thus, in these ferrites a consistent assignment of all the major transitions in the 2.0 to 5.0 eV energy range to either IVCT or ISCT transitions is made. © 1998 American Institute of Physics. [S0021-8979(98)22011-1]

I. INTRODUCTION

The identification and assignment of magneto-optical (MO) active transitions in spinel ferrites have been a subject of debate for many years. The identification of transitions is complex as in these compounds many bands overlap. In addition, the electronic structure of transition metal oxides such as ferrites is complex^{1,2} which has resulted in a variety of interpretations of the observed transitions. Recently, we have unraveled the MO-Kerr spectrum of Fe_3O_4 between 0.7 and 4.0 eV by rigorous fitting of all four elements of the dielectric tensor of Fe_3O_4 simultaneously, using the equations of the elements of the dielectric tensor which describe the basic line shapes of transitions in the microscopic theory (Lorentz-type lineshape). In addition, the complete dielectric tensors of Fe_3O_4 and of partially Mg^{2+} or Al^{3+} substituted Fe_3O_4 were fitted with only one set of parameters for all samples. The influence on the intensity of transitions of the gradual substitution of Fe^{2+} and/or Fe^{3+} provided evidence that the major transitions in Fe_3O_4 can be assigned to intervalence charge transfer and intersublattice charge transfer transitions (IVCT and ISCT, respectively).³ IVCT transitions are transitions in which an electron, through optical excitation, is transferred to a neighboring cation. IVCT transitions between Fe^{3+} ions on different crystallographic sites are traditionally called ISCT transitions.⁴ For reasons of clarity we will continue to refer to these transitions as ISCT transitions. (In our discussions parenthesis denote tetrahedral A sites and square brackets octahedral B sites.)

Thus far multiple interpretations have been reported for the ferrites $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$, MgFe_2O_4 , NiFe_2O_4 , and CoFe_2O_4 . We will discuss them in chronological order. Krinchik *et al.* reported the off-diagonal element of the dielectric tensor of $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$ between 2 and 5 eV.⁵ These authors reported

also the off-diagonal elements of NiFe_2O_4 , CoFe_2O_4 , CoCrFeO_4 between 1 and 5.4 eV and the equatorial Kerr effect of $(\text{Fe})[\text{NiCr}]_4\text{O}_4$.^{5,6} In addition to the transitions already identified in $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$ and MgFe_2O_4 an additional broad band near 3 eV was identified in NiFe_2O_4 . This band was assigned to the CF transition ${}^3A_{2g}(\text{F}) \rightarrow {}^3T_{1g}(\text{P})$ of octahedrally coordinated Ni^{2+} . However, in this interpretation the disappearance of this transition in $(\text{Fe})[\text{NiCr}]_4\text{O}_4$ cannot be accounted for. From the observed influence of Al^{3+} and Cr^{3+} substitution on the equatorial Kerr spectra of NiFe_2O_4 and CoFe_2O_4 , Krinchik *et al.* conclude that the major transitions in $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$ and MgFe_2O_4 are ISCT transitions.

Subsequently, Višnovsky *et al.* reported the diagonal and off-diagonal elements of the dielectric tensor of MgFe_2O_4 and reflectivity and polar Kerr spectra of $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$ between 2 and 5.5 eV. These authors assigned the transitions identified to oxygen (2p) to iron (3d) charge transfer transitions.⁷ From the work of Bocquet *et al.*, however, it follows that this is an unlikely interpretation as the oxygen to iron charge transfer transitions are centered around 6 eV (Ref. 2) in agreement with previous reports.^{4,8} In 1983 Zhang *et al.* reported the diagonal (0.5–12 eV) and off-diagonal (0.5–5 eV) elements of the dielectric tensor of $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$ and MgFe_2O_4 . The identified bands were assigned to $3d^n \rightarrow 3d^{n-1}4s$ orbital promotion transitions.⁸ However, these transitions are parity and partly spin forbidden and can, therefore, not account for the relatively large oscillator strength (10^{-3}) of the transitions observed in these ferrites. Finally, the MO-Kerr spectrum of CoFe_2O_4 has been extensively studied by Martens and co-workers.^{9,10} Two narrow diamagnetic transitions at 0.8 and 2.0 eV were identified and assigned to CF transitions [${}^4A_2 \rightarrow {}^4T_1(\text{F})$ and ${}^4A_2 \rightarrow {}^4T_1(\text{P})$] of tetrahedrally coordinated Co^{2+} . A broad paramagnetic band also at 2.0 eV was assigned to a $[\text{Co}^{2+}] \rightarrow [\text{Fe}^{3+}]$ IVCT transition. The broad diamagnetic band in the region above 3 eV remained unresolved.

FIG. 1. (a) The measurement Ref. 7 and the fits of the real and imaginary part of the off-diagonal element of the dielectric tensor, ϵ'_{xy} and ϵ''_{xy} , of MgFe_2O_4 . (b) The measurement Ref. 5 and the fits of the real and imaginary part of the off-diagonal element of the dielectric tensor, ϵ'_{xy} and ϵ''_{xy} , of NiFe_2O_4 .

Here we report a study of the MO spectra of $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$, MgFe_2O_4 , NiFe_2O_4 , and CoFe_2O_4 and identify the major transitions. For this purpose, we have taken the elements of the dielectric tensor of these compounds from literature and applied the same method used to resolve the MO spectrum of Fe_3O_4 .³

II. RESULTS AND DISCUSSION

First, we examine MgFe_2O_4 . We applied the method used to resolve the spectrum of Fe_3O_4 to the diagonal and off-diagonal element of the dielectric tensor of MgFe_2O_4 obtained from Refs. 8 and 7, respectively. The off-diagonal element and the fits are presented in Fig. 1(a). The set of transitions identified in MgFe_2O_4 is listed in Table I. To

assign these transitions, we compare them to the transitions found in Fe_3O_4 .³ The MO spectrum of Fe_3O_4 consists of two sets of transitions: IVCT transitions involving Fe^{2+} and Fe^{3+} and the ISCT involving two Fe^{3+} ions located on different crystallographic sites. Since the Fe^{2+} ions present in Fe_3O_4 are replaced by the nonmagnetic Mg^{2+} , the ISCT transitions should be the only remaining major transitions. Substitution of one ion with another may distort the lattice resulting in a shift in energy of the ISCT transitions. However, replacing Fe^{2+} with Mg^{2+} only has a small effect on the lattice since the lattice parameter of MgFe_2O_4 matches closely the lattice parameter of Fe_3O_4 . We conclude from our fit [Fig. 1(a)] that the MO-Kerr spectra of MgFe_2O_4 can be explained in a manner consistent with our interpretation of Fe_3O_4 , based on ISCT transitions, as suggested previously.¹¹

For $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$ the elements of the dielectric tensor were obtained from Refs. 8 and 5. The set of transitions identified from our fits is listed in Table I. The same three major bands as in MgFe_2O_4 could be identified. The fact that the intensities in $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$ are substantially higher than in MgFe_2O_4 is to be expected as this compound contains a larger amount of $[\text{Fe}^{3+}]$, which is one of the participating ions in the transition.⁵ Thus also the MO-Kerr spectra of $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$ can be explained in a manner consistent with Fe_3O_4 based on ISCT transitions.

Only the off-diagonal element of the dielectric tensor of NiFe_2O_4 was available.⁵ The off-diagonal element and fit are presented in Fig. 1(b). The results of the fit are given in Table I. Again we observe the same set of ISCT transitions as in the previous samples. In addition, we observe an additional strong, relatively broad transition at 2.9 eV. This transition cannot be assigned to a CF transition. First of all, CF transitions of ions on octahedral sites are parity forbidden for any ion. Second, transitions of Ni^{2+} on tetrahedral sites cannot occur, as the NiFe_2O_4 sample used, is reported to be completely inverse, as expected for NiFe_2O_4 .¹² Third, CF transitions of Fe^{3+} on tetrahedral sites do not occur, as the term of a free Fe^{3+} ion is nondegenerate ($L=0$). Further-

TABLE I. The main MO-active transitions in MgFe_2O_4 , $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$, NiFe_2O_4 , and CoFe_2O_4 , between 0.5 and 5.0 eV. Listed are transition energy, ω (eV), linewidth, Γ (eV), intensity, $(\epsilon_{xy})_{\text{max}}$, and assignment. Typical error bars for ω , Γ , and $(\epsilon_{xy})_{\text{max}}$ are ± 0.02 eV; ± 0.03 eV, and ± 0.002 , respectively. (Note that the parenthesis denote tetrahedral coordination and square brackets octahedral coordination.)

more, this additional transition cannot be due to an oxygen $2p$ to metal $3d$ charge transfer transition. Such a transition should occur at an energy of 6 eV (Ref. 1) and it would be both broader and more intense than the observed band. Therefore, we assign this transition to an IVCT transition between $[\text{Ni}^{2+}]$ and $[\text{Fe}^{3+}]$.¹³ This is consistent with the strength and width of similar transitions in Fe_3O_4 .³ Furthermore, the energy of an IVCT transition between two different cations is expected to be substantially higher than that between two identical cations which in Fe_3O_4 occurs at 0.55 eV.³

Evidence that the transition at 2.9 eV is indeed due to an IVCT transition between $[\text{Ni}^{2+}]$ and $[\text{Fe}^{3+}]$ comes from the equatorial Kerr spectrum of $(\text{Fe})[\text{NiCr}]\text{O}_4$ between 1 and 5.4 eV.⁶ No transitions whatsoever are found in this spectrum, ruling out that the transition at 2.9 eV in NiFe_2O_4 is due to a CF transition of Ni^{2+} . The absence of this transition is, however, in line with an IVCT involving $[\text{Fe}^{3+}]$. This also supports our assignment of the remaining transitions in NiFe_2O_4 to ISCT transitions. Another indication that all transitions in NiFe_2O_4 are similar transitions involving $[\text{Fe}^{3+}]$ is the influence of Al^{3+} substitution on the MO spectrum of $\text{NiAl}_x\text{Fe}_{2-x}\text{O}_4$ ($0 \leq x \leq 1.2$) which remains completely inverse up to $x = 1$.¹⁴ The entire spectrum remains unchanged up to $x = 0.3$, then the intensity of the entire spectrum decreases homogeneously.

The complete dielectric tensors of CoFe_2O_4 and $\text{CoAl}_x\text{Fe}_{2-x}\text{O}_4$ ($x = 0.1, 0.6, 1$) were taken from Martens *et al.*^{9,10} All four elements of the dielectric tensors of CoFe_2O_4 and $\text{CoAl}_x\text{Fe}_{2-x}\text{O}_4$ were fitted simultaneously with only one set of parameters for all spectra, thus allowing trends in intensity upon Al^{3+} substitution to be observed. The results of the fits for CoFe_2O_4 are shown in Table I. Our assignment of the first three transitions is identical to the assignment made previously.⁹ The first two are assigned to the CF transitions ${}^4A_2 \rightarrow {}^4T_1(\text{F})$ and ${}^4A_2 \rightarrow {}^4T_1(\text{P})$ (Co^{2+}) on A sites. These are the only two CF transitions which are allowed from the singlet 4A_2 ground state of (Co^{2+}) (note that CF transitions from octahedrally coordinated $[\text{Co}^{2+}]$ are parity forbidden). The third is assigned to a $[\text{Co}^{2+}] \rightarrow [\text{Fe}^{3+}]$ IVCT transition. The remaining two transitions are two of the three ISCT transitions observed in each of the three previous investigated compounds. The third ISCT near 2.6 eV, present in all other spinel ferrites discussed so far, is obscured in CoFe_2O_4 due to the intense band at 2.2 eV. To the evidence presented for the assignment of the CF transitions proposed by Martens *et al.*,⁹ one can add the observed changes in intensity as reported for $\text{CoAl}_x\text{Fe}_{2-x}\text{O}_4$.¹⁴ $\text{CoAl}_x\text{Fe}_{2-x}\text{O}_4$ changes from inverse to normal spinel between $x = 0$ to $x = 1.2$, i.e., Co^{2+} migrates to the tetrahedral site. The intensity of the transition at 1.9 eV increases for $x = 0.0$ to 0.8 then decreases for $x > 0.8$. The intensity of the transition at 2.2 eV slightly increases for $x = 0.3$ then decreases. This enhancement effect on IVCT transitions of a small amount of Al^{3+} , resulting from perturbation of the octahedral symmetry, was observed also in Fe_3O_4 containing a small amount of Al^{3+} .³ The bands between 3 and 5 eV

decrease steadily for $0 \leq x \leq 1.2$. The dependencies of the intensities of the IVCT transition (2.2 eV) and the ISCT transitions on the degree of Al^{3+} substitution tend, as expected, towards zero for CoAlFeO_4 in our fits. As discussed by Martens *et al.* the gradual decrease in intensity for the CF transitions of (Co^{2+}), however, is not straightforward. Their claim is that the sharp drop in Curie temperature for the series causes this. The fact that the energy of the IVCT transition is considerably larger than that of the first IVCT in Fe_3O_4 can be attributed to the fact that the IVCT is in this case between cations with different nuclei. The fact that the energy of this IVCT is smaller compared to the energy of the observed IVCT in NiFe_2O_4 is also not unexpected, if we take into account the relative energy position of the $3d$ bands.¹

III. CONCLUSIONS

The common feature of all spinel ferrites of the general type $\text{M}_x\text{Fe}_{3-x}\text{O}_4$ with Fe^{3+} ions on both tetrahedral and octahedral sites is a set of ISCT transitions at 2.6, 3.5, and 4.0 eV. This is evident from Table I for those spinel ferrites, where M is the nonmagnetic Mg^{2+} and Li^+ as well as for those where M is the magnetic Ni^{2+} and Co^{2+} . (This even applies to $\gamma\text{-Fe}_2\text{O}_3$, where M is in fact a vacancy.¹⁴) Whether these transitions dominate the spectrum depends on the presence of other contributing transitions. For $\text{M} = \text{Mg}$, Li , or other nonmagnetic ion (or vacancies), the set of ISCT transitions is the main feature. In Fe_3O_4 several IVCT transitions between $[\text{Fe}^{2+}]$ and Fe^{3+} are main contributors.³ In NiFe_2O_4 an IVCT between $[\text{Ni}^{2+}]$ and $[\text{Fe}^{3+}]$ at 2.9 eV is a main contributor. In CoFe_2O_4 CF transitions of tetrahedrally coordinated Co^{2+} and an IVCT transition between Co^{2+} and Fe^{3+} contribute significantly below 2.5 eV. These assignments are consistent with our interpretation of the MO spectra of Fe_3O_4 .

The magneto-optical (MO) Faraday effect of one-dimensional photonic crystals (1D-PCs) composed of Bi-substituted yttrium-iron-garnet films and dielectric films such as SiO₂ and TiO₂ films were studied theoretically. Because of considerable localization of light, these media exhibit a very large MO effect. For instance, when the film structure is chosen to be appropriate for supporting the localization of light, the 1D-PC films can possess a huge Faraday rotation angle reaching to $-28 \text{ deg}/\mu\text{m}$ at $\lambda = 1.15 \mu\text{m}$. The analysis reveals that the MO characteristics of the 1D-PC films are almost governed by the degree of localization of light, which can be controlled by varying the number of reflection layers in the films. © 1998 American Institute of Physics.

[S0021-8979(98)44711-X]

I. INTRODUCTION

Recently, we have shown theoretically that a large magneto-optical (MO) Faraday effect takes place in bigyrotropic magnetic films with disordered multilayer structure¹⁻³ due to the weak localization of light;⁴ the films of interest are composed of Bi-substituted yttrium-iron-garnet (Bi:YIG) layers and SiO₂ layers which are piled up in a disordered sequence. These studies strongly indicate that films exhibiting a considerably large MO effect can be obtained if the film structure meets the so-called one-dimensional photonic crystal with a defect⁵ (1D-PC), or equivalently, optical microcavity,⁶ because the localization effect of light in these particular media is very large.

In this study, therefore, MO properties of films with 1D-PC structures have been investigated in detail so as to confirm the above consideration theoretically. First, the relation between the MO effect and the localization of light is explained to demonstrate the unique properties of the films. Then the key parameters governing the optical and MO properties of the films are elucidated. Based on these results, practical 1D-PC films with (SiO₂/TiO₂) $\times k$ /Bi:YIG/(TiO₂/SiO₂) $\times k$ structures are proposed.

II. MODEL AND THEORY

Since the procedure for analyzing the properties of films with multilayer structures has been described elsewhere in detail,¹⁻³ let us confine ourselves to an outline of the analysis by focusing on the expression of film structures and the matrix approach which enables us to handle various multilayer films systematically.

As shown in Fig. 1, we consider a magnetic multilayer film with N layers extending boundlessly in the X - Y plane.

The film is composed of Bi:YIG and SiO₂ layers which are generally stacked in an arbitrary sequence. The individual magnetic and dielectric single layers are assumed to have thicknesses d_M and d_S , respectively. Total thickness of film D is then expressed as $D = N_M d_M + N_S d_S$ with the numbers of magnetic and dielectric layers N_M and $N_S = N - N_M$, respectively. The film structure is designed by a binary number b^N with an N digit; for instance, $b^N = 101110...01$, where each digit of b^N corresponds to each layer of the film, and "1" and "0" are assigned to the magnetic and dielectric layers, respectively. When b^N and the density of magnetic material, $P_M = N_M d_M / D$, are given, the film structure is uniquely specified.

The properties of the films are clarified by solving Maxwell's equations with the bigyrotropic dielectric tensor for the magnetic layers under the electromagnetic boundary conditions imposed at all discontinuous planes. This is rather tedious, but is easily achieved by means of the matrix approach.¹ With this method, the state transition of light through one layer is expressed by a 4×4 complex matrix called the state matrix. Let Φ_M and Φ_S be the state matrices

FIG. 1. Multilayer film composed of Bi:YIG and SiO₂ layers.

^{a)}Electronic mail: inouem@riec.tohoku.ac.jp

FIG. 2. Maximum Faraday rotation angle $(\theta_F)_{\max}$ vs packing density P_M at which $(\theta_F)_{\max}$ was obtained.

of the magnetic and dielectric layers; the state transition of light through the whole film is written as

$$\tau(Z_0 + D) = \Phi_M \cdot \Phi_S \cdot \Phi_S \cdot \dots \cdot \Phi_M \cdot \tau(Z_0) \equiv \Phi \cdot \tau(Z_0), \quad (1)$$

where $\tau = (E_X, E_Y, H_X, H_Y)$ with the tangential components of the electromagnetic field with respect to the discontinuous plane. Note that the multiple sequence of Φ_M and Φ_S in Eq. (1) corresponds to the sequence of 1 and 0 in b^N . For all the films, no matter what the stacking sequence and the stacking number are, the state of outgoing light $\tau(Z_0 + D)$ is obtained from the state of incident light $\tau(Z_0)$ multiplied from the left by Φ . Then, from the relation between $\tau(Z_0 + D)$ and $\tau(Z_0)$, optical and MO properties of the films, such as the transmissivity T and the Faraday rotation angle θ_F , are determined numerically.

The numerical calculations were performed using the typical values of dielectric tensors: for the Bi:YIG layers, $\epsilon_1 = 5.58$ and $\epsilon_2 = -1.98 \times 10^{-3}$ at $\lambda = 1.15 \mu\text{m}$ ($\theta_F \approx -0.1 \text{ deg}/\mu\text{m}$); for the SiO₂ layers $\epsilon_S = 2.5$ and for the TiO₂ layers $\epsilon_T = 4.7$.

III. MO EFFECT AND LOCALIZATION OF LIGHT

To demonstrate the unique MO properties of the films, we show in Fig. 2 the maximum Faraday rotation angles $(\theta_F)_{\max}$ of all 16 layer films ($b^{16} = 0000 \sim [FFFF]$, $P_M = 0.0 \sim 1.0$) as a function of the density P_M at which $(\theta_F)_{\max}$ was obtained. Among the films, three particular films, labeled (a), (b), and (c), exhibit considerably large Faraday rotation. The binary parameters of these films are (a) $b^{16} = 10101010101010101$, (b) 1010100111010101 , and (c) 1010101111101010 , where the strong correlation among the

FIG. 4. Distribution of the light field in the film with $P_M = 0.4585$ in Fig. 3.

film structures exists: more than two Bi:YIG layers are sandwiched between the alternatively formed Bi:YIG and SiO₂ layers. This then indicates that the large MO effect of the films can be characterized by the film structures. In fact, films of this type exhibit very unique transmissivity T and Faraday rotation θ_F as shown in Fig. 3: at $P_M = 0.4585$, both T and θ_F of the film with $b^{34} = 101010101010101010101010101010101$ increase simultaneously and remarkably. In this case, θ_F of the film surprisingly exceeds $-16 \text{ deg}/\mu\text{m}$, the value of which is about 160 times larger than that of a Bi:YIG single layer film.

As shown in Fig. 4, light propagating in the film with $P_M = 0.4585$ in Fig. 3 is localized to a large extent at the center of the film, suggesting that the unique properties of the film originate from the localization effect of light. In Fig. 5, the transmission responses of the film to the independent incidences of lights with linear polarization and the right-hand and left-hand polarizations are shown. As is clearly seen in Fig. 5, the film structures (or P_M values) for which the circularly polarized lights are localized are slightly different from each other. This gives rise to the large rotation angle for the linearly polarized light, because the linearly polarized light decomposes into the circularly polarized lights as eigenmodes of lights in Bi:YIG layers.

IV. FILMS WITH 1D-PC STRUCTURES

The above results strongly indicate that the stronger the localization effect of light, the larger the MO effect of the

FIG. 3. Transmissivity T and Faraday rotation angle θ_F of the film with $b^{34} = 101010101010101010101010101010101$ vs density P_M at $\lambda = 1.15 \mu\text{m}$, where the film thickness D is $5 \mu\text{m}$.

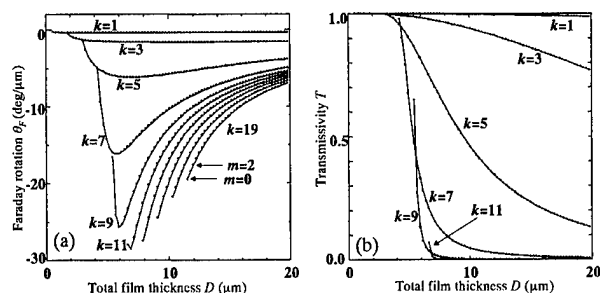

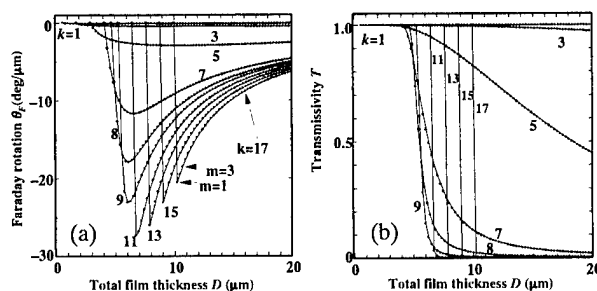

FIG. 5. Transmissivity of the film in Fig. 3 for three cases of incidence of lights with linear polarization and right-hand and left-hand circular polarizations.

FIG. 6. Bi:YIG/SiO₂ multilayer film with the 1D-PC structure.

films. In Fig. 3, the thicknesses of the Bi:YIG and SiO₂ layers of the film with $P_M=0.4585$ are evaluated as $d_M=0.127\ \mu\text{m}$ and $d_S=0.169\ \mu\text{m}$, respectively. These values are close to the one-fourth wavelength of light ($\lambda=1.15\ \mu\text{m}$) in each medium: for the Bi:YIG (SiO₂) layer, the diffraction index n_M (n_S) is about 2.36 (1.58) and the $\lambda/4n_M$ ($\lambda/4n_S$) is about $0.121\ \mu\text{m}$ ($0.182\ \mu\text{m}$). The structure of the film with $P_M=0.4585$ is then close to the 1D-PC structure, where the center cluster of Bi:YIG layers acts as an active layer while the other layers act as reflection layers of light.

With this respect, the optical and MO properties of the 1D-PC films were examined in detail by employing the film structure illustrated in Fig. 6: an active Bi:YIG layer with thickness of $D_M=m\lambda/2n_M$ ($m=0,1,2,\dots$) is sandwiched between two reflection layers which are composed of a k pair ($k=1,2,3,\dots$) of the Bi:YIG/SiO₂ layers related by $d_M n_M = d_S n_S = \lambda/4$. In Fig. 7, for cases of reflection layers composed of odd-pair layers, θ_F and T of the films are depicted as a function of the total film thickness D . The properties of the 1D-PC films are very sensitive to the values of k and m which determine the film structures. In general, by increasing the number of reflection layers, k , the transmissivity decreases while the Faraday rotation increases drastically. This is due to the fact that the localization of light is strengthened by increasing the value of k . The largest Faraday rotation in this system is $-28\ \text{deg}/\mu\text{m}$ when $k=11$ and $m=1$, and whose value is 280 times larger than that of a Bi:YIG single layer film. However, the transmissivity of this film is about 2%, and hence the use of this film in transmission mode is difficult. An appropriate choice of film structure then becomes necessary depending on the applications, where the

FIG. 7. Faraday rotation and transmissivity of the 1D-PC films with $(\text{Bi:YIG}/\text{SiO}_2) \times k/\text{Bi:YIG}/(\text{SiO}_2/\text{Bi:YIG}) \times k$ structure.FIG. 8. Faraday rotation and transmissivity of the 1D-PC films with $(\text{SiO}_2/\text{TiO}_2) \times k/\text{Bi:YIG}(\text{TiO}_2/\text{SiO}_2) \times k$ structure.

key parameters are the number of reflection layers, k , and the thickness of the center active layer which is governed by m . To achieve this, film design with a genetic algorithm is useful.⁷

To obtain the above 1D-PC films formation of many Bi:YIG layers, without losing their good MO properties, is needed. This is, however, rather troublesome, and 1D-PC films without this difficulty are favored. This is indeed fulfilled by the 1D-PC films with $(\text{SiO}_2/\text{TiO}_2) \times k/\text{Bi:YIG}/(\text{TiO}_2/\text{SiO}_2) \times k$ structures, where the thickness of the center Bi:YIG film is chosen to be $m\lambda/2n_M$ while the thicknesses of the TiO₂ and the SiO₂ layers, d_T and d_S , satisfy the relation $d_T n_T = d_S n_S = \lambda/4$ with the refractive index n_T of the TiO₂ layers. In these films, a Bi:YIG single-layer film is sandwiched between two dielectric multilayers acting as the reflection layers of light, and the MO interaction takes place in the center Bi:YIG film. Although the number of Bi:YIG layers in these 1D-PC films is greatly reduced in comparison with the previous 1D-PC films, these films exhibit almost comparable performance to that of the previous one. For instance, as shown in Fig. 8, the maximum Faraday rotation of the film reaches nearly $-28\ \text{deg}/\mu\text{m}$. This, in turn, indicates that the contribution by the Bi:YIG layers that comprise the reflection layers of light to the MO effect is considerably small, and that the MO effect of the 1D-PC film is governed by the degree of localization of light.

The ordered structures in Fe_3O_4 kerosene-based magnetic fluid films were discovered and the magneto-chromatic effects were also observed under various magnetic fields. In this report, we studied the relationship between the ordered structures and the magneto-chromatic effects theoretically and experimentally. The nearly perfect hexagonal structures with the distance between two columns d in μm range for our magnetic fluid thin films offer a two-dimensional tunable magnetic fluid grating in the visible light region. By using a grating model, the diffraction patterns for visible lights at certain incident angle θ , wavelength λ , and column distance d , were calculated. Experimentally, it was found that the conditions of the observed light around the direction perpendicular to the plane of film coincide with the calculated results. Therefore, the magneto-chromatic effects resulting from the ordered structures of the tunable magnetic fluid grating were confined. © 1998 American Institute of Physics. [S0021-8979(98)22111-6]

I. INTRODUCTION

Due to its potential application, optical phenomena of magnetic fluids subjected to an external magnetic field were put under extensive study recently. Those works were concentrated on the optical transmission and optical scattering of magnetic fluid films, both with or without an external magnetic field. For the first area of research, it mainly utilized the character of the light absorption by magnetic fluid. The optical transmittance decreases with the increase of the film thickness as light passes through a magnetic fluid film. Several optical devices were developed including display devices^{1,2} and optical switches.³⁻⁵ Also, by varying the refractive index across a ferrofluid thin film resulting from a temperature gradient and/or a magnetic field, a diffraction ring can be altered.⁶ In contrast, for the second area of research, the nature of the one-dimensional (1D) ordered structure of magnetic fluid films under a parallel external magnetic field was used. When a magnetic fluid thin film is subjected to an external magnetic field parallel to the plane of film, the particles in the film start to agglomerate and form chains along the direction of field. Thus, the magnetic fluids become optically anisotropic.⁷ Reflection and Bragg diffraction may occur as a light ray incident obliquely on the thin film; birefringence and polarization may occur as light rays passing normally through the thin film. The light scatter intensity of these phenomena increases with an increase in both the magnetic field strength and particle concentration, and it tends to saturate at higher fields.⁸ By measuring the intensity as a function of magnetic field strength and time, the relaxation time and viscosity of the magnetic fluid drops

were calculated.⁹ Also, the spacings between 1D periodic chains formed from the droplets of magnetic emulsion under a parallel magnetic field were able to be measured because the chains gave rise to a strong Bragg diffraction, and the interaction forces between colloidal particles were determined based on the force-distance law.¹⁰ Moreover, they also reported that the thin film appeared colored in the back-scattering direction as the thin film was illuminated by a white light source.

In addition to the previous areas of research, other optical principles, such as light diffraction and interference, may also play an important role in the application if a 2D ordered structure in the magnetic thin film can be produced. In our past work,¹¹ 2D ordered structures in Fe_3O_4 kerosene-based magnetic fluid film were discovered. As a result, we had the magneto-chromatic effects observed under various magnetic fields.¹² In order to understand this consequence and to better manipulate the color from the grating, we study the relationship between the ordered structures and the magneto-chromatic effects theoretically and experimentally.

II. EXPERIMENTAL DETAILS

The magnetic fluid used in this work was a kerosene-based Fe_3O_4 ferrofluid prepared by the coprecipitation technique. The saturated magnetization of the sample is 10.58 emu/g and the particle size is around 100 Å.¹¹ The magnetic fluid was sealed in a 4 cm × 1 cm rectangular glass cell with a thickness of 6 μm to form a ferrofluid thin film. The experiment was performed at room temperature.

Throughout the experiment, the magnetic fields perpendicular to the film plane were generated by a pair of solenoids and were controlled by a personal computer. The applied field measured with a gaussmeter was uniform;

FIG. 1. A typical image of a hexagonal structure of magnetic fluid thin film and its FFT transformation. The column distance d_{FFT} can be calculated from $d_{\text{FFT}} = 2\pi/r$, where r is the radius of the FFT ring.

deviations of the field strength in the region of the film were found to be less than 1%. To generate white lights, a halogen lamp with Cokin 82B filter was used. The light ray was made near parallel by passing them through a telescope and a pair of optical lenses, and reflected by a mirror located beneath the thin film.

The images of the ordered hexagonal structures were taken by using a videoscope located above the thin film. They were used to calculate the column distances by fast Fourier transform (FFT) transformation. Figure 1 shows an example of an image of the hexagonal structure and its FFT transformation. For the measurement of the wavelength spectrum, an optical fiber located above the thin film in the direction perpendicular to the plane of the film was used to pick up the light that passed through the thin film and to feed the signal into a spectrometer for scanning the wavelength of the diffraction patterns. The scanned light signal was sensed by a photomultiplier, to which a program was used to change the voltage for the compensation of its sensing sensitivity.

III. RESULTS AND DISCUSSION

When an applied perpendicular magnetic field reaches a critical value H_h (80 Oe for the sample), a 2D column array is formed in a homogeneous magnetic fluid thin film. Figure 2 is a plot of the distance d between two columns as a function of the final magnetic field strength (H_f) and its ramping rate (dH/dt) with the initial magnetic field strength $H = 0$ Oe. It indicates that the distance decreases as both the magnetic field strength and the ramping rate increase. These distances d are in μm range. In this range, diffraction phenomena occur as a parallel white light ray passing through the film and a well saturated monocolored light can be observed. By varying the magnetic field strength and/or the

FIG. 2. The column distance d vs final magnetic field H_f with various ramping rate (dH/dt).

ramping rate resulting in a change of the distance d , the color of the film can be altered. In our laboratory, a large areal monocolored light over the entire visible light range can be produced and well manipulated. This phenomenon can be called the “magneto-chromatic effect.”

To analyze the transmitted lights, the wavelength spectrum of the transmitted light through the magnetic fluid film with zero field ($H_f = 0$ Oe) and the spectra of lights through the ordered structures of magnetic fluid film under the final field $H_f = 200$ Oe with various (dH/dt) were shown in Fig. 3. It reveals that each curve contains two peaks: the first one with wavelength shorter than 600 nm and the second one higher than 600 nm. These two peaks and their associated distributions move toward the shorter wavelength as (dH/dt) increases. The intensities of the first peak decrease as the ramping rate increases; contrarily the second peak has an opposite trend. At low ramping rate the color appeared is mainly due to the first peak, and as the ramping rate in-

FIG. 4. Diagram for a grating model.

creases the color due to the second peak becomes more obvious.

To illustrate this magneto-chromatic phenomenon, a grating model was used as shown in Fig. 4. In this model, d is the separation distance between the adjacent slits with the distance between columns as defined above, θ is the angle formed between the incoming light ray and the direction perpendicular to the plane of the film, θ' is the angle formed between the diffracted rays and the direction perpendicular to the plane of the film, and N is the total number of magnetic particle columns diffracting the light. After diffraction, the intensity of the light, I , is

$$I \propto \frac{\sin^2(N\varphi/2)}{\sin^2(\varphi/2)},$$

where φ is the phase difference. The condition under which the light intensity I becomes maximum is the same as that under which the light becomes brightest after diffraction through the film. The condition is

$$\frac{\varphi}{2} = \frac{\pi}{\lambda} d(\sin \theta + \sin \theta') = \kappa\pi,$$

where κ is a non-negative integer and λ is the wavelength of light.

If the θ and θ' are not both equal to zero, the condition of $\kappa=0$ will never occur. Under the condition of $\kappa=1$, d will be related to λ by $d(\sin \theta + \sin \theta') = \lambda$. If λ is within the range of visible light, then the same d will allow only light with a wavelength of λ/κ for $\kappa=2,3,\dots$ to pass through the film. However, light with these wavelengths is outside the visible spectrum.

Based on the relationship of $d(\sin \theta + \sin \theta') = \lambda$, the wavelength becomes shorter as d decreases. When the (dH/dt) increases, the column distances decrease (as shown in Fig. 2) resulting in a shift of the wavelength of transmitted light toward shorter wavelength (as shown in Fig. 3) after light diffracted. As indicated before, the curves in this Fig. 3 contain two major peaks. Apparently, the first peak is the first-order maximum and the second peak may be contributed by a higher ordered effect which is due to the larger incident angle and viewing angle than those of the first-ordered effect. This higher order effect is mainly induced from the setup and can be improved by limiting only the light with a single incident angle and viewing angle in the experiment.

TABLE I. A list of curves 2–7 with various ramping rates (dH/dt) in Fig. 3 and their corresponding color, first-ordered peak wavelength λ_{peak} , column distance d_{FFT} calculated from FFT transformation, and that fitted from grating model d_{grating} .

Curve No. in Fig. 3	dH/dt ($H_f=200$ Oe)	Color	λ_{peak} (nm)	d_{FFT} (μm)	d_{grating} (μm)
2	$dH/dt=5$ Oe/s	yellow-green	565	2.15	2.17
3	$dH/dt=10$ Oe/s	green	545	1.97	1.99
4	$dH/dt=20$ Oe/s	blue	520	1.81	1.84
5	$dH/dt=30$ Oe/s	violet	500	1.73	1.76
6	$dH/dt=50$ Oe/s	violet-red ^a	485	1.70	1.72
7	$dH/dt=100$ Oe/s	red ^a	470	1.66	1.68

^aIn this case, the higher order red light becomes significant.

Also, the distance d between columns can be calculated by fitting the incident angle θ from data points and using the peak wavelength λ_{peak} that was obtained at $\theta' \approx 0^\circ$. Table I compares the distances $d_{\text{FFT}} (= 2\pi/r, r$ the radius of FFT ring) calculated from the FFT transformation of hexagonal structures and the distances $d_{\text{grating}} (= \lambda_{\text{peak}}/\sin \theta)$ from the first-ordered peak wavelength of the spectra, and they show a good agreement. Therefore, the magneto-chromatic effects resulting from the ordered structures of the tunable magnetic fluid grating were confined.

IV. CONCLUSION

As a 2D hexagonal structure formed in a magnetic thin film under a perpendicular magnetic field, the distances between particle columns can be altered by changing the field strength and/or the rate of change of field strength. The column distances are in μm range and are capable of diffracting the visible light. By changing the column distance, the color of light after interference can be varied. Thus, well saturated colors were observed and their corresponding wavelength spectra were measured. This phenomenon can be explained by a grating model theoretically. Our experiments have demonstrated the magneto-chromatic effects of magnetic fluid thin films by changing the rate of strength of the externally applied perpendicular magnetic field. This work exposed the possibility of using the magnetic fluid as an alternative material for optical devices.

A spin polarized current has been injected into high T_c superconductors resulting in a significant reduction in the superconductor's critical current. Such injection may serve as the basis of a new class of superconducting devices for control, switching and amplification. Preliminary results using both Permalloy and CMR materials as injectors are presented. © 1998 American Institute of Physics. [S0021-8979(98)42011-5]

I. INTRODUCTION

The superconductivity in thin films can be strongly influenced by the injection of a spin-polarized current from a magnetic material. The effect has been found to occur in both low T_c (Sn) and high T_c ($\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$) superconductors when either a ferromagnetic material, permalloy ($\text{Ni}_{0.8}\text{Fe}_{0.2}$), or a colossal magnetic material LaSrMnO (LSMO) is used as the source of polarized quasiparticles. Control experiments showed that unpolarized current from a nonmagnetic metal had comparatively little effect. A phenomenological model in which the energy gap of the superconductor is strongly perturbed by the presence of excess spin polarized electrons is presented which is found to mimic the experimental results.

Nonequilibrium superconductivity has previously been studied by injecting a current from a *nonmagnetic* source. The influence of unpolarized, nonequilibrium quasiparticles (unpaired electrons) on the superconducting energy gap has been examined experimentally and theoretically.¹ Injection of unpolarized quasiparticles has also been used to make devices such as the CLINK and the QUITERON. Johnson and Silsbee first demonstrated² that a current injected from a ferromagnet into a nonmagnetic metal maintained a net spin polarization in the latter. It has also been shown that spin polarization persists into the interior of the low T_c superconductor, Nb.³ Evidence for spin injection from a ferromagnetic film into films of the high T_c superconductor YBCO was subsequently reported.⁴ While noting the inherently lower charge carrier densities in YBCO, the authors did not report the effect of the nonequilibrium spin population on the electronic transport properties of the superconducting film. Such effects are described in this article.

II. EXPERIMENTAL ARRANGEMENT

Figure 1 shows the typical experimental design. The top electrode (injector) is the source of the quasiparticles: If it is magnetic, the quasiparticles are polarized, whereas quasiparticles injected from a nonmagnetic film (control) are unpolarized.

The barrier can be either a metal film or low transmission tunnel barrier. The lower film is the superconductor. For some materials the sequence of the layers is reversed. A bias current I_{qp} generates an excess number density of quasiparticles, dn_{qp} , in the superconductor which suppresses the energy gap and diminishes the critical current of the film. The supercurrent flowing through the superconductor (I_T) is thus "pinched off" by the injected quasiparticle current, I_{qp} .

III. RESULTS FOR PERMALLOY

The first experiments proceeded with a gold metallic layer serving as a chemical barrier. The YBCO samples were 200 nm thick and 3 mm wide. The normal metal was 50 nm thick and 1 mm wide. The ferromagnetic film was permalloy, 100 nm thick and 1 mm wide. All films were produced by pulsed-laser deposition. Measurement of the modification of the superconducting order parameter by I_{qp} began with determination of the critical current I_c at 77 K in the absence of a bias current. This was achieved by measuring the current-voltage ($I-V$) curve of the YBCO stripe and choosing I_c at a voltage drop of 1 μV . $I-V$ curves were then taken as a function of I_{qp} injected through the Au/permalloy lead (po-

FIG. 1. Schematic representation of a spin injection device. Current I_{qp} passes from the magnetic film (upper) into the underlying superconducting film and decreases the supercurrent of the latter by decreasing the energy gap in the dark region.

FIG. 2. Current-voltage curves observed for a Permalloy/Au/YBa₂Cu₃O₇ sample at 77 K. Open circles: curve in the absence of quasiparticle injection. Open triangles: curve with an unpolarized current of 10 mA. Solid circles: curve with a polarized current of 10 mA.

larized injection) or through the Au lead (unpolarized injection).⁵ In the latter case, the exclusively Au contact produced quasiparticle injection and served as a control. Permalloy was chosen as the ferromagnetic source because the conduction electrons involved in the transport current have a high degree (45%) of spin polarization.⁶

Differences in I_c between the runs were attributed to the differing effects of unpolarized versus polarized quasiparticle injection. Results are shown in Fig. 2 for our best sample. This figure demonstrates in a very striking way how a comparatively small amount of polarized quasiparticle current ($I_{qp} = 10$ mA) strongly depresses the transport current of the superconductor by depressing I_c to about 80 mA. By comparison, the same amount of unpolarized bias current has almost no effect on I_c . Similar behavior to that shown in Fig. 2 has been observed in other samples, but the differences in I_c between the Au and permalloy contacts were not as large.

IV. RESULTS FOR LSMO

Samples were made by first depositing an LaSrMnO film, then an insulating layer of SrTiO, and finally a layer of YBCO using pulsed laser deposition. No control film was deposited in these samples. 4-terminal resistance measurements indicate the YBCO had a transition temperature of 86 K with a width of about 5 K. The LSMO was also characterized resistively, and was found to have a peak temperature of approximately 260 K. All measurements were performed with the substrates emersed in liquid nitrogen to insure good thermal conductivity to the bath. The effect of the spin polarization, as shown in Fig. 3, was quite large. One way to

FIG. 3. Current-voltage curves observed for a LaSrMnO/SrTiO/YBa₂Cu₃O₇ sample at 77 K. Proceeding from left to right I_{qp} was: 2.0, 1.8, 1.6, 1.4, 1.2, 1.0, 0.8, 0.4 and 0.0 mA.

characterize the current gain is to plot I_c of the YBCO film as a function of I_{qp} . As shown in the inset to Fig. 4, the gain is roughly constant at 35.

A significant portion of the effect, however, may be due to heating. Slight suppression of I_c when current passed only through the LSMO was observed. In addition, the interface between the YBCO and LSMO was found to have a resistance of approximately 3 Kohm. At the highest currents shown in Fig. 3, some 22 mW was dissipated in the substrate. The relative importance of heating is being studied by varying the resistance of the magnetic stripe and by varying the resistance of the junction between it and the superconducting film. More recently, samples with improved materials have been fabricated. The T_c of the YBCO was increased to 90 K, with a transition width of only 2 K. The LSMO peak temperature increased to 300 K. Unfortunately, the devices so made show little or no gain. It is now clear that the characterization of the interface needs to be better addressed. Is the spin polarization maintained across the interface? What is the mechanism for transport across the interface? Is it tunneling of spins, or Ohmic conduction through resistive microshorts? These are the questions which are currently being investigated with samples of smaller geometries.

V. THEORY

The injection of excess quasiparticles into the superconductor weakens the pairing correlations, thereby reducing the superconducting energy gap Δ_k . The BCS gap equation, which is valid for both equilibrium and nonequilibrium situations, quantifies the energy gap reduction,

$$\Delta_k = \sum_{k'} V_{kk'} \frac{\Delta_{k'}}{2E_{k'}} [1 - f_{\uparrow}(E_{k'}) - f_{\downarrow}(E_{k'})], \quad (1)$$

where $E_k = (\epsilon_k^2 + \Delta_k^2)^{1/2}$ and $f_{\sigma}(E_k)$ is the spin-dependent

quasiparticle distribution function (QDF). The spin index σ identifies either the spin up (\uparrow) or down (\downarrow) orientation. For an isotropic gap Eq. (1) can be rewritten

$$-\ln \left[\frac{\Delta(T)}{\Delta_{\text{eq}}(0)} \right] = \int_{-\infty}^{\infty} d\epsilon \frac{f_{\uparrow}(E(\epsilon)) + f_{\downarrow}(E(\epsilon))}{2E(\epsilon)}, \quad (2)$$

where $E(\epsilon) = (\epsilon^2 + \Delta^2)^{1/2}$ and $\Delta_{\text{eq}}(0)$ is the zero-temperature equilibrium superconducting gap. The determination of the QDF's are vital for understanding the properties of a superconductor driven out of equilibrium. This can be difficult in general, but a useful ansatz is that the QDF has the form of a modified Fermi function

$$f_{\sigma}(E) = 1 / [\exp(E - \mu_{\sigma}^*) / k_B T + 1], \quad (3)$$

where $\sigma = (\uparrow, \downarrow)$ and the quantities μ_{σ}^* and T^* are used to parameterize the increased number of excess quasiparticles beyond the thermal equilibrium population. In equilibrium $\mu_{\uparrow}^* = \mu_{\downarrow}^* = 0$ and $T^* = T$. The number density of excess quasiparticle is given by

$$\delta n_{\sigma} = n_{\sigma} - n_{\text{eq}} = N(0) \int_{-\infty}^{+\infty} d\epsilon [f_{\sigma}(E(\epsilon)) - f_{\text{eq}}(E(\epsilon))], \quad (4)$$

where $N(0)$ is the single-spin density of states at the Fermi surface, n_{eq} and f_{eq} are the equilibrium single-spin quasiparticle density and distribution functions, respectively.

The QDF in Eq. (3) is a combination of two phenomenological models of nonequilibrium superconductivity: the μ^* and T^* models. Each is applicable in different circumstances. The μ^* model is a reasonable starting point when quasiparticles thermalize with low-energy phonons more often than they recombine into pairs and when the escape rate of phonons from the sample is large.⁸ In these limits the quasiparticles are in steady state at T but have an excess number denoted by the increased chemical potential μ^* . In the opposite limit, where recombination of quasiparticles is more likely than thermalization and the escape rate of phonons is small, the T^* model is applicable.⁹ The small escape rate causes the "phonon bottleneck" where recombining pairs emit a phonon of energy $\omega > 2\Delta$ but that phonon cannot easily leave the sample and, also, has sufficient energy to break a pair. The phonon bottleneck drives the phonons with energy $\omega > 2\Delta$ out of equilibrium to an effective temperature T^* . The excess quasiparticles acquire a steady-state distribution which is the same as equilibrium except that the temperature T^* is higher.

In the analysis of the CLINK device, the T^* model was used instead of the μ^* model since the phonon escape rate was considered small and, for tunnel injection of quasiparticles, recombination tends to dominate thermalization. However, spin-polarized injection of quasiparticle changes many of these considerations by introducing the spin-relaxation rate into the problem. Since it requires both up and down-spin quasiparticles to recombine into a pair, a spin-polarized population must first undergo spin relaxation then recombination. Spin relaxation has a relatively slow time scale compared to intrinsic recombination and thermalization times; thus, quasiparticles have the opportunity to thermalize to the ambient temperature T . With thermalization dominant,

FIG. 4. The critical current I_c normalized by the critical current in the absence of I_{qp} as a function of I_{qp} . The quasiparticle current is normalized by the density of states and the gap at $T=0$, and by the spin relaxation, τ_{sr} . The upper curve is for a temperature $T=0$; the middle for $T=0.53 T_c$ and the lowest curve for $T=0.88 T_c$. Inset: Measured I_c of the YBCO sample as a function of spin polarized current I_{qp} .

the μ^* model becomes viable to the extent that the quasiparticle injection is spin-polarized. If the phonon escape rate is also large then the μ^* -model alone [$(T^*=T)$ in Eq. (3)] should be sufficient. In Fig. 4 we show the results of a calculation of the suppression of the critical current due to the injection of a 100% spin polarized current.

VI. CONCLUSION

A large depression of the supercurrent in YBCO films is observed when a current from a spin polarized film is introduced. Results from the most recent experiments indicate that heating may dominate the behavior of these devices. Work continues to determine what fraction of the effect is due to heating and what part due to spin polarized quasiparticle injection, and to study the effects of the interface on spin injection.

Magnetoquenched superconducting valve

T. W. Clinton^{a)} and Mark Johnson

Naval Research Laboratory, Washington, DC 20375

A superconducting switch has been developed in a simple bilayer cross strip geometry using the magnetic fringe field of a ferromagnetic film to control the critical current in an underlying superconducting bridge. The magnetization of the ferromagnet is rotated in the plane of the film to vary the magnitude of the fringe field locally applied to the superconductor from negligible to substantial values. In the latter case, the magnetization is oriented such that the magnetic poles are along the edges of the cross strip directly above the superconductor. The large fringe field near the poles suppresses superconductivity over a length of order microns, giving rise to superconducting weak link behavior. A large modulation of the critical current is observed. The effect is demonstrated in the low T_c superconductors Pb ($T_c = 7.3$ K) and Sn ($T_c = 3.9$ K). Fabrication of the device involves minimal processing. Applications as a high speed switch, amplifier, nonvolatile storage cell, and controllable weak link are possible. © 1998 American Institute of Physics. [S0021-8979(98)15811-5]

There has been considerable effort over a period of decades to produce low power electronic devices using superconducting elements. In general, these devices are based on the principle of switching a superconducting component between its zero resistance state and its normal state with non-zero resistance. The superconducting field effect transistor (SuFET) was one of the first viable three terminal superconducting devices¹ and has had a recent revival with applications to the high T_c superconductors.² Its operation is based on modulating superconductivity with the application of an electric field via a gate voltage. Other three terminal devices, such as the controllable weak link (CLINK)³ and the quasiparticle injection tunneling effect (QUITERON)⁴ rely on quasiparticle injection to locally drive the superconductor out of equilibrium and suppress superconductivity. Both devices, developed in low T_c materials, showed current gain and the QUITERON was demonstrated to possess high switching speeds and power gain. These devices eventually lost favor because their gain was limited, though there is renewed interest in nonequilibrium effects generated by spin polarized quasiparticle injection in both low T_c (LTS) and high T_c (HTS) materials.⁵ Josephson junction based devices fabricated in LTS have found success as superconducting quantum interference device (SQUID) field sensors,⁶ and the rapid single flux quantum (RSFQ) logic circuitry has demonstrated fast switching and nonvolatile storage capabilities.⁷ Equivalent devices in HTS materials have not yet proven viable.

Recently we presented a novel superconducting switch in a bilayer thin film structure where the superconducting state of low T_c Sn ($T_c = 3.9$ K) was switched on or off by the magnetic fringe field of a ferromagnetic film.⁸ In this article, we present further results on Sn, as well as the first demonstration of the effect in Pb ($T_c = 7.3$ K). The critical current in a thin film of either Sn or Pb is controlled by the magnetic fringe field of a ferromagnetic film deposited as a cross strip

over the superconductor. The large fringe field near the poles of the ferromagnet depresses superconductivity over a length of order microns, creating superconducting weak links and a correspondingly lower critical current. A large modulation of the critical current is observed. A semiquantitative magneto-static model of the fringe fields and supporting data are presented.

The device geometry is depicted in Figs. 1(a) and 1(b). The superconductor (S) is Sn or Pb, the ferromagnet (F) is permalloy (Py), and the insulator, a native oxide layer of about 10-Å-thick SnO or PbO, respectively, inhibits a proximity effect between F and S. The magnetization \mathbf{M} of the thin Py film is constrained to the film plane. After \mathbf{M} has been saturated along the $\hat{x}(\hat{y})$ axis, the dipolar external field generated by the remanent magnetization \mathbf{M}_r can be characterized by magnetic poles at the edges of the film parallel to $\hat{y}(\hat{x})$. Typical field lines are sketched in Figs. 1(a) and 1(b). The field magnitude is large at positions near the poles and weak at remote positions. In Fig. 1(a), the magnetization of F is oriented along \hat{x} , the cross strip is extended beyond the width of the S bridge, and the magnetic field at S is weak and parallel to the film plane. In Fig. 1(b), the magnetization is oriented along \hat{y} , the magnetic poles are along the edges of the cross strip directly above the superconductor, and the field at S is perpendicular to the plane with substantial magnitude.

Figure 1(c) depicts a cross-sectional view of the device with \mathbf{M}_r of the F film along \hat{y} . The external field \mathbf{B} can be calculated from the distribution of magnetic poles and is represented by arrows and dotted field lines. To good approximation, the surface pole density of magnitude M poles/cm² can be represented as a line source located at the middle of the end surface and having line density $\lambda = d_F M$. The field magnitude in the vicinity of the line source varies inversely with distance r ,

$$B = \frac{4\pi M d_F}{2\pi r} = \frac{2M d_F}{r}. \quad (1)$$

^{a)}Electronic mail: clinton@anvil.nrl.navy.mil

FIG. 1. (a) Prototype device geometry with F film remanent magnetization oriented along \hat{x} ; and (b) along \hat{y} . (c) Cross section of device geometry showing magnetic fringe field of F film and affect on underlying superconductor.

Typical dimensions in these structures are $d_F = 2000 \text{ \AA}$ for the F film thickness, $d_s = 400 \text{ \AA}$ for S, and the saturation magnetization of Py is $4\pi M_s \approx 11 \text{ kG}$, so the peak value of perpendicular field in the superconductor directly beneath one of the poles is of the order of a few kG and the decay width is less than a micron. In practice, the edges of our F films have some degree of roughness and the spatial extent of the fringe fields is expected to be broader, accompanied by a proportionately diminished value of peak magnitude. Nevertheless, a portion of S beneath an edge of F should be significantly affected by the relatively strong magnetic fringe fields when \mathbf{M} is along \hat{y} , and the short length scale of this magnetoquench should result in weak link behavior. Indeed, this "quench valve" can control the current flow in S, as is demonstrated below.

The Sn device consists of a 400-\AA -thick Sn film defined using a shadow mask to be 2 cm long and $400 \text{ }\mu\text{m}$ wide. The transition onset is $T_c \approx 3.9 \text{ K}$, the width is typically 100 mK or less, and the perpendicular upper critical field $H_{c2} \approx 850 \text{ Oe}$ ($T = 1.5 \text{ K}$). The F film layer is a cross strip of Py evaporated by e beam from a $\text{Ni}_{0.8}\text{Fe}_{0.2}$ source, with dimensions 2300 \AA thick, $400 \text{ }\mu\text{m}$ wide, and approximately $500 \text{ }\mu\text{m}$ long and extending about $50 \text{ }\mu\text{m}$ beyond the edge of the bridge on each side. The Pb device consists of a 350-\AA -thick Pb bridge ($T_c \approx 7.3 \text{ K}$, $\Delta T_c \leq 100 \text{ mK}$) defined photolithographically to be $100 \text{ }\mu\text{m}$ long and $5 \text{ }\mu\text{m}$ wide, with a 2150-\AA -thick Py cross strip. A native oxide layer ($\approx 10 \text{ \AA}$) is grown on the surfaces of Sn and Pb by glow discharge in oxygen before depositing the Py cross strip. SQUID magnetometer measurements determine the saturation magnetization of the Py to be $4\pi M_s = 11.5 \text{ kOe}$ at $T = 2.5 \text{ K}$. The co-

FIG. 2. (a) Sn-SnO-Py structure, voltage vs current at $T = 3.80 \text{ K}$ ($T_c = 3.9 \text{ K}$) for two remanent magnetization orientations M_y and M_x . (b) Voltage vs current at $T = 2.95 \text{ K}$ for two remanent magnetization orientations.

ercivity depends on several fabrication parameters and varies over all samples from $H_c \approx 2$ to 50 Oe . A field on the order of 100 Oe is applied along the chosen axis to orient \mathbf{M} , and is then reduced to zero prior to the transport measurement, unless noted otherwise. The data for the Pb device are measured in a cryostat with optical access to the sample as part of a magneto-optic Kerr effect photometer. Results similar to those presented in this article have been confirmed in more than ten samples.

The effect is demonstrated by the voltage versus current plot presented in Fig. 2 for a Sn-SnO-Py structure. In Fig. 2(a), the current-voltage (I - V) characteristics are plotted at $T = 3.80 \text{ K}$, just below T_c , where the righthand curve (M_x) was measured with \mathbf{M}_r oriented along \hat{x} as in Fig. 1(a); using a $1 \text{ }\mu\text{V}$ criterion the critical current is $I_{cx} = 3 \text{ mA}$. The lefthand curve (M_y) corresponds to \mathbf{M}_r along \hat{y} as in Fig. 1(b), and now the critical current is $I_{cy} = 0$. The I - V trace is linear for small voltages with a slope of $59 \text{ m}\Omega$. From the normal state resistance of the Sn bridge ($R_l \approx 27 \text{ }\Omega/\text{cm}$ just above T_c), $59 \text{ m}\Omega$ corresponds to a normal region about $20 \text{ }\mu\text{m}$ long, or a $10 \text{ }\mu\text{m}$ length under each edge of the F film. At lower temperatures as H_{c2} of Sn increases, these normal segments become narrower and should act like weak links in the superconducting bridge when they are comparable to the coherence length $\xi(T)$. Indeed, the data at lower temperatures are consistent with this. In Fig. 2(b) at $T = 2.95 \text{ K}$, well below T_c , we have $I_{cx} = 90 \text{ mA}$ (M_x) while $I_{cy} = 20 \text{ mA}$ (M_y),

FIG. 3. Pb-PbO-Py structure, voltage vs current at $T = 6.2$ K ($T_c = 7.3$ K) for two remanent magnetization orientations M_x and M_y , as well as with an applied field $H_y = 40$ Oe to saturate Py magnetization, $M_y \approx M_s$. Inset: hysteresis loop of Py layer measured with magneto-optic Kerr effect photometer at room temperature. The Kerr rotation angle θ_K , and thus the Py magnetization M , is proportional to the photodiode voltage given in μV .

a 4.5-fold decrease. Thus, there is still a large suppression of I_c in switching magnetization states, but a nonzero I_{cy} indicates there is phase coherence across the quenched regions. Weak link behavior, such as Shapiro steps in the I - V characteristics as a function of rf power, and periodicity of I_c in applied magnetic flux, ϕ , have also been observed.⁹

Next, we turn to our Pb-PbO-Py structure. In Fig. 3, the voltage versus current characteristic at $T = 6.2$ K is plotted. The righthand curve (M_x) was measured with M_r oriented along \hat{x} as depicted in Fig. 1(a), while the middle curve (M_y) corresponds to M_r along \hat{y} as shown in Fig. 1(b). Consistent with the Sn data, I_c is suppressed when the remanent magnetization M_r is along \hat{y} (M_y). The inset of Fig. 3 is a hysteresis loop measured on the Py layer at room temperature with a magneto-optic Kerr photometer. The photodiode voltage is proportional to the Py magnetization M . The coercivity of the Py is roughly 5 Oe, and the magnetization is saturated by 40 Oe. At low temperatures, where the transport measurements are done, the loop is somewhat broader. It can also be seen from the figure that the remanent magnetization is only about half the saturation magnetization, $M_r \approx M_s/2$. From Eq. (1), the field at the Py film edge is proportional to M so the effect will be strongest with the magnetization saturated. The lefthand curve is measured with a small applied field along the y direction, $H_y = 40$ Oe, to saturate the magnetization. The applied field is parallel to the plane of the film and has no direct effect on the superconductivity at this temperature. However, I_c is suppressed even further as the Py magnetization is now saturated and the concomitant increase in perpendicular field at the edge of the film causes an

even greater quench of superconductivity in Pb, consistent with our magnetostatic model. Thus, it is desirable to produce ferromagnetic films with a square hysteresis loop, $M_r \approx M_s$, which is a tractable materials issue but not within the scope of this work.

The novel effect presented here has characteristics that make it promising for device applications. Since the switch requires zero quiescent power to maintain its state, the device is intrinsically a nonvolatile memory element. This coupled with its weak link nature puts it in a new class of Josephson-like devices: nonvolatile controllable weak links. Because the effect arises from the edge of a F film, a device can be made on a micron scale without degrading its performance. The speed of the device is set by magnetic domain switching times in the F film and flux relaxation in the superconductor. Domain switching imposes a limit between 1 GHz and 1 THz depending on material, while flux relaxation depends on the dimensions of the superconductor and for a micron scale device, these rates should be possible in a variety of materials.¹⁰ Small currents in a contiguous write wire can be used to switch the magnetization of the F film, and this integrated device should be capable of current, voltage, and power gain, and therefore capable of performing logic functions. Finally, fabrication of the device involves minimum processing. Since the effect does not involve transport, the nature of the F-S interface is not important and device fabrication is relatively simple.

In summary, we have demonstrated a novel superconducting switch using the magnetic fringe field of a ferromagnetic film to control the critical current in an underlying superconducting bridge. The effect is robust at temperatures well below the superconducting transition. The effect is modeled as the result of superconducting weak links being generated,⁹ and as such the switch is in a new class of Josephson-like devices. A semiquantitative magnetostatic model is in very good agreement with our results.⁸

One viable approach for transistor-like high- T_c three terminal devices is the quasiparticle injection device (QPID). We have fabricated $\text{Au/YBa}_2\text{Cu}_3\text{O}_7/\text{LaAlO}_3/\text{Nd}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ (NSMO) and $\text{Au/YBa}_2\text{Cu}_3\text{O}_7/\text{LaAlO}_3/\text{LaNiO}_3$ (LNO) heterostructures on (100) LaAlO_3 substrates by pulsed laser deposition for studies of quasiparticle injection effects in high- T_c superconducting thin films. The effect of the injection of spin-polarized quasiparticles from a ferromagnetic NSMO gate was compared to that of unpolarized quasiparticles from a nonmagnetic metallic LNO gate. A current gain greater than nine has been attained for spin-polarized QPIDs, which is an order of magnitude larger than the gain of spin unpolarized QPIDs. Such large effects could be useful in a variety of active high- T_c /colossal magnetoresistance heterostructure devices. © 1998 American Institute of Physics. [S0021-8979(98)42111-X]

I. INTRODUCTION

There has been significant research on the study of transistorlike superconducting three terminal devices such as flux-flow transistors,¹ electric field effect transistors,² anti-vortex Josephson junction transistors,³ and quasiparticle injection devices (QPIDs).^{4–10}

QPID is a nonequilibrium device. The injection of quasiparticles into a superconductor (S) creates a local nonequilibrium state which changes the quasiparticle spectrum and hence alters the superconducting order parameter.^{11,12} This usually causes a suppression in the critical current (I_c) density. QPIDs with low- T_c superconductors (LTS) have been extensively investigated using all kinds of injection sources to create the desired nonequilibrium transport for device applications.¹³ HTS, with their lower carrier densities, are more sensitive to quasiparticle injection. But the gain has been low. Nevertheless, these devices are attractive because their speed, which is limited by the effective quasiparticle relaxation time, may be of the order of 10–100 GHz.^{8,10} It should be noted that, in all the prior work, the quasiparticle injection sources are the free electrons and carry no spin polarization from the normal metal (N) gates through the insulating barriers (I).

However, quasiparticles can be spin-polarized. Tedrow and Meservey discovered that a ferromagnetic metal electrode (F) could inject spin-polarized quasiparticles into a superconductor.¹⁴ Johnson and Silsbee demonstrated that spin-polarized carriers injected into a normal metal diffuse over a distance δ_s , from the $F-N$ interface, and have a spin lifetime of T_1 (e.g., ~ 560 ps in Nb).¹⁵ Recently, an F metal layer of $\text{La}_{2/3}\text{Sr}_{1/3}\text{MnO}_3$ has been used as an injection source.¹⁶ The spin-polarized quasiparticles were indirectly

injected into a 600 Å thick $\text{DyBa}_2\text{Cu}_3\text{O}_7$ superconducting channel and a calculated current gain (G), defined as the ratio of critical current suppression to injection current ($G = \Delta I_c / I_{\text{inj}}$), of ~ 1 was achieved. Soon after, Dong *et al.*¹⁷ developed an *in situ* technique using pulsed laser deposition to fabricate $S-I-N$ and $S-I-F$ heterostructures for the studies of spin-polarized quasiparticle injection effects, where S is $\text{YBa}_2\text{Cu}_3\text{O}_7$ (YBCO), I is LaAlO_3 (LAO), F is $\text{Nd}_{2/3}\text{Sr}_{1/3}\text{MnO}_3$ (NSMO) and N is LaNiO_3 (LNO). The device geometry was designed for electronic applications with all quasiparticles directly injected into S . A current gain as large as five was attained for spin-polarized injection. This is 10 to 30 times larger than the gain of unpolarized injection devices. It strongly suggests that a new mechanism of pair breaking, associated with spin-polarized electrons, may be responsible for the suppression of I_c .

II. EXPERIMENTAL METHODS

The two structures used in this study are made on (100) LAO substrates by pulsed laser deposition. One is YBCO/LAO/NSMO ($S-I-F$) and the other is YBCO/LAO/LNO ($S-I-N$), where the NSMO is ferromagnetic below 170 K and acts as a spin-polarized injection source, while the LNO is metallic with quasiparticles carrying no spin polarization. The thickness of the LAO barrier layer is varied from 0–560 Å, and the other layers had the same thickness in both device structures: 1000 Å for the top YBCO layer and 2000 Å for the bottom NSMO or LNO layer. All thicknesses were determined and calibrated by Rutherford backscattering spectroscopy (RBS). The advantage of this comparison between the two types of structures, in contrast to comparing the manganite gate with a conventional metallic gate,¹⁶ is that the density of the carriers, the effect of lattice matching, the natural barrier of the interfaces, channel thickness, etc., are

^{a)}Currently at Read-Rite Corp., 44100 Osgood Road, Fremont, CA 94539.

FIG. 1. (a) X-ray diffraction pattern of an *in situ* trilayer YBCO/LAO (400 Å)/NSMO. (b) Ion beam channeling and random Rutherford backscattering spectra with 3 MeV He^+ ion.

similar for both of our structures. This allows us to directly compare the injection effect of spin-polarized and unpolarized quasiparticles.

The laser energy density is 2 J/cm^2 for the deposition of NSMO and LAO and 1.5 J/cm^2 for YBCO.¹⁸ The substrate temperature is 600°C for LNO and 800°C for the other layers. During the deposition, the oxygen pressure is kept at 150 mTorr for YBCO and 400 mTorr for the other layers and is increased to 400 Torr during slow cooling of the samples. The x-ray diffraction pattern for the resulting *S-I-F* QPID is shown in Fig. 1(a). As can be seen, all layers are highly *c*-axis oriented. The YBCO is in the desired high- T_c 123 phase and the NSMO is in the cubic-type perovskite CMR phase, although there are three weak peaks which may arise from either (012) YBCO or BaCuO_2 . Figure 1(b) shows 3 MeV He^+ ion Rutherford random backscattering and channeling spectra which show a minimum yield of $\chi_{\min} \approx 16\%$ for the trilayer of *S-I-F*, indicating reasonably good crystallinity.

We have implemented a multilevel photolithography process involving image-reverse resist, selective wet etching, ion milling, thermal evaporation and lift-off procedure to integrate the devices on a small scale.^{17,18} The geometry of the devices allows the quasiparticles to be injected fully and directly into the *S* channel. Thus the effect can be studied quantitatively. The size of the devices is $20\text{--}250 \mu\text{m}$ wide and $220 \mu\text{m}$ long. The inset of Fig. 2 shows a schematic of our QPID configuration and a circuit for the injection measurements. The gate is biased with a Keithley 224 programmable current source. A standard four-probe technique is used for the electrical transport measurements of the *S* layer. In order to isolate the top Au from the bottom layer, a 2200 \AA thick rf-sputtered SiO_2 is deposited over the devices for passivation.

Figure 2 shows the temperature dependence of the resistivities of the individual layers in the devices: ferromagnetic

FIG. 2. R - T curves of YBCO (squares), NSMO (circles), and LNO (triangles) individual layers. YBCO has a T_c of 89 K, NSMO has a ferromagnetic transition at 170 K, and LNO is metallic. The inset is a schematic of a QPID.

NSMO, metallic LNO, and superconducting YBCO. The ferromagnetic transition occurs at 170 K for NSMO, confirmed by magnetization measurement. The resistivities of the NSMO and LNO layers are $\sim 1000 \mu\Omega \text{ cm}$ and $\sim 300 \mu\Omega \text{ cm}$ at 100 K, respectively, which are a little higher than that of the YBCO layer. The T_c of YBCO varies between 80 and 89 K in different devices. Vertical transport measurements show a contact resistance of order $10^{-4} \Omega \text{ cm}^2$ for a very thin LAO barrier layer.

III. RESULTS AND DISCUSSIONS

As described in Ref. 17, the I - V curves of all devices were found to be nonsymmetric. They exhibit a shift with respect to the zero current point in addition to showing a suppression in I_c . For each I - V curve there are two I_c values, positive critical current I_{cp} and negative critical current I_{cn} using a voltage criterion of $+2 \mu\text{V}$ or $-2 \mu\text{V}$, respectively. We defined the current shift (I_{shift}) in the I - V curves as $(I_{cp} + I_{cn})/2$ and I_c to be the half width of the zero voltage plateau, namely $I_c = (I_{cp} - I_{cn})/2$. This definition of I_c has thus taken into account the subtraction of the current from the shift caused by the injection current. Note that changing the direction of the injection current causes a shift in the opposite direction.

For all the devices we found a linear relationship between I_{inj} and I_{shift} , namely, $I_{\text{inj}} = -I_{\text{shift}}$, which is a consequence of the injection current totally participating in the current flow in the YBCO layer with zero resistance. In other words, if the injection current were parallel to the transport current in YBCO, the channel current would increase with increasing injection current. If the injection current flowed antiparallel to the channel current, the channel current would decrease since the injection current is subtracted from the transport current. If one takes the shift into account, the I - V curves are perfectly symmetric.

Figure 3 shows the I_c suppression versus injection current at different temperatures for both *S-I-F* and *S-I-N* QPIDs. In the *S-I-F* QPID [Fig. 3(a)], the I_c can be sup-

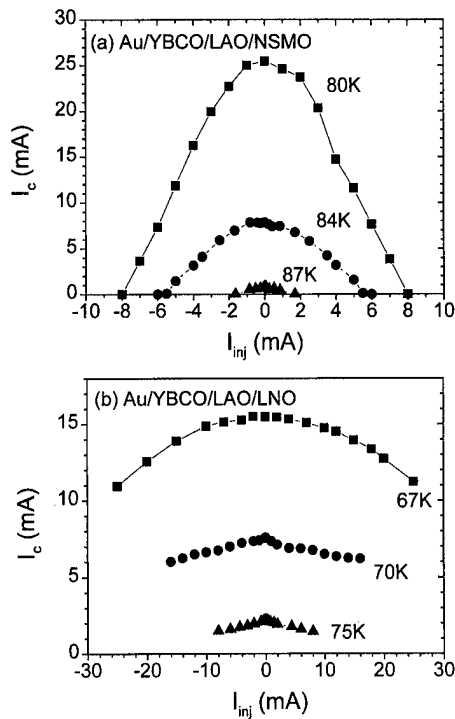

FIG. 3. Dependence of the critical current of both (a) Au/YBCO/LAO/NSMO ($S-I-F$) and (b) Au/YBCO/LAO/LNO ($S-I-N$) QPIDs, each with a 80 Å thick LAO barrier, on the injection current at different temperatures.

pressed to zero while in the $S-I-N$ QPID the I_c suppression is less than 30% even with injection currents in excess of 25 mA [Fig. 3(b)]. The current gain is 3.2 at 80 K for this particular $S-I-F$ QPID with an 80 Å thick LAO barrier. This is an order of magnitude larger than that for the $S-I-N$ spin-unpolarized QPID ($G \leq 0.3$) with the same LAO barrier thickness. In addition, we have systematically studied the effect as a function of the barrier thickness (details will be published elsewhere). A maximum gain of 9.3 was achieved at 84 K for an $S-I-F$ QPID with a 160 Å thick LAO barrier, which corresponds to a differential gain (dI_c/dI_{inj}) of 14. Typically, current gain is about 2–9 for barriers thinner than 200 Å. Upon increasing the barrier thickness beyond 200 Å, the current gain decreases very fast ($G \leq 1$). This shows that the optimal gain could be attained with a barrier thickness between 40–160 Å. The injection power density ($P_{inj} = J_{inj}^2 \times R_{area} \approx 1 \text{ W/cm}^2$) for $S-I-F$ QPIDs is even less than that for $S-I-N$ QPIDs. Based on these observations, the role of any significant thermal effect may be ruled out.

Since the sole difference between $S-I-N$ and $S-I-F$ QPIDs is spin-unpolarized injection in $S-I-N$ and spin-polarized injection in $S-I-F$, the observation of significantly larger gains for $S-I-F$ QPIDs suggests that spin-polarized quasiparticles generate a substantially larger nonequilibrium population. Although there is no formal theory describing nonequilibrium quasiparticle injection effect in HTS, let us do a semiquantitative analysis. The injected quasiparticle density is given by $\Delta n = J_{inj} \tau_r(T) / et$, where e is the electron charge and t is the thickness of YBCO.⁵ From experimental J_{inj} data and the estimation of

$\tau_r(T) \sim 10 \text{ ps}$, the maximum injected quasiparticle density is found to be of order 10^{17} cm^{-3} . We find that this density should be sufficiently large enough to suppress I_c ,^{6,17} giving a current gain of order 0.01–0.1 for $S-I-N$ QPIDs. However, the observed gain is of order 1 for $S-I-N$ QPIDs and the number of Cooper pairs in YBCO is a few orders of magnitude larger than the number of injected quasiparticles. This strongly indicates that the mechanism of pair breaking due to the injected spin-polarized quasiparticles could be very different from that of unpolarized quasiparticles in high- T_c oxides. We also found that lowering the temperature further increases the current gain, which is consistent with the measured temperature dependence of the quasiparticle relaxation time τ_r .¹⁹

Extended x-ray absorption fine structure measurements of nonsuperconducting $\text{PrBa}_2\text{Cu}_3\text{O}_{6.9}$: Evidence against Ba site Pr substitution

V. G. Harris,^{a)} D. J. Fatemi, V. M. Browning, and M. S. Osofsky
Naval Research Laboratory, Washington, District of Columbia 20375

T. A. Vanderah
National Institute of Standards and Technology, Gaithersburg, Maryland

Extended x-ray absorption fine structure (EXAFS) measurements on nonsuperconducting $\text{PrBa}_2\text{Cu}_3\text{O}_{6.9}$ are reported. Theoretical Pr L_{II} EXAFS data, calculated for the case of Y-site and Ba-site occupation, were least-squares fit to the experimental Pr L_{II} EXAFS. Results indicate that the Pr ions overwhelmingly occupy the Y sites. These results present a serious challenge to models which rely on Ba-site Pr substitution as an explanation for the lack of superconductivity in $\text{PrBa}_2\text{Cu}_3\text{O}_{6.9}$. [S0021-8979(98)35711-4]

Despite more than a decade of intense research, the transport properties of the high temperature superconductors (HTS) are not well understood. Although the mechanism responsible for superconductivity is still under debate, most theories agree that the origin of superconductivity resides in the Cu–O planes which are common to all of the HTS. One exception is the oxygen or “charge reservoir” model proposed by Blackstead and Dow (BD).¹

In the $\text{RBa}_2\text{Cu}_3\text{O}_{7-\delta}$ ($R=Y$ and rare earths) or “123” compounds, the Cu–O chains serve as the charge reservoir. All of the 123 materials form metallic superconductors with the exception of $\text{PrBa}_2\text{Cu}_3\text{O}_{7-\delta}$ (PBCO) which, until recently, was reported to be insulating and nonsuperconducting. Nonsuperconducting PBCO presents a challenge to the BD model which predicts that this material should superconduct; therefore, recent reports of superconductivity in Pr materials which reportedly have the orthorhombic 123 structure have been touted as evidence in favor of BDs model.² However, these reports have yet to be independently verified, and the structure has yet to be confirmed by rigorous crystallography. Despite these results, it is still the general consensus that stoichiometric PBCO, when synthesized in a form isostructural with superconducting 123 materials, is both nonmetallic and nonsuperconducting.

In this article, we present extended x-ray absorption fine structure measurements of the nonsuperconducting compound $\text{PrBa}_2\text{Cu}_3\text{O}_{6.9}$ (PBCO). These results provide new insight regarding the structure of PBCO and confirm that Pr resides on the Y sites and is unlikely to occupy the Ba site in this material. This result is in conflict with assumptions made by several theories including the BD model.

A polycrystalline $\text{PrBa}_2\text{Cu}_3\text{O}_{6.9}$ powder was prepared by high-temperature solid-state reaction of reagent grade BaCO_3 , Pr_6O_{11} , and CuO in air within an alumina combustion boat. The starting materials were intimately mixed by grinding prior to each heating. As reported by others,³ a large number of reheatings, in this case 12, were required to obtain a single-phase sample for which all peaks in the powder

x-ray diffraction pattern could be accounted for. The mixture was heated first at 880 °C, twice at 925 °C, three times at 935 °C, and then six times at 945 °C. The final powder was pressed to ~1 g, 13 mm diameter disks that were sintered in air at 900 °C cooled at a rate of 75 °C/h to 500 °C, soaked at 500 °C for 15 days, and then furnace cooled to ambient temperature.

A sample disk was ground to a fine powder and subjected to x-ray powder diffraction analysis using $\text{Cu } K_\alpha$ radiation. All observable reflections in the x-ray powder pattern were used to refine the orthorhombic unit cell using a least-squares method.⁴ Compared with the single-crystal structural data reported for $\text{PrBa}_2\text{Cu}_3\text{O}_6$ and $\text{PrBa}_2\text{Cu}_3\text{O}_{6.9}$,⁵ the c parameter [11.712(1) Å] and unit cell volume [178.33(3) Å³] indicate an oxygen content of 6.9.

The x-ray absorption coefficient encompassing the Pr and Ba L absorption edges and the Cu K absorption edge was measured in transmission mode⁶ using the NRL beamline (X23B),⁷ at the National Synchrotron Light Source (Brookhaven National Laboratory, Upton, NY). Beamline X23B employs a double-crystal, fixed-exit monochromator with a pair of Si (111) crystals. Harmonic rejection is achieved by an upstream mirror that reflects only radiation of 10 keV or less. The extended x-ray absorption fine structure (EXAFS) data were collected when the storage ring energy was 2.5 GeV with a ring current between 110–250 mA. Because Pr K absorption occurs near 42 keV, too high an energy for most synchrotron EXAFS beamlines to operate, and the Pr L_{III} edge is contaminated by the Ba L_I edge fine structure, the Pr and Ba L_{II} absorption edges were used for EXAFS analysis.

The EXAFS analysis reported here involves the least-squares fitting of the phase and amplitude of experimental k -space data using a linear combination of simulated Pr(Y)-site and Pr(Ba)site L_{II} EXAFS data. The simulated L_{II} EXAFS data were generated using the multiple-scattering *ab initio* FEFF 6 codes of Rehr *et al.*,⁸ where the FEFF input files were generated using ATOM 4.2 codes of Ravel.⁹ These data

^{a)}Electronic mail: harris@zoltar.nrl.navy

FIG. 1. Magnetic susceptibility of $\text{PrBa}_2\text{Cu}_3\text{O}_{6.9}$ sample as a function of temperature for several applied fields indicating lack of a superconducting state.

will henceforth be referred to as the FEFF data. The goodness-of-fit was determined numerically via the χ^2 fitting parameter.

The input parameters to FEFF codes were the lattice parameters determined by x-ray diffraction (XRD), the Debye temperature (Θ_D), and an amplitude reduction coefficient (S_0^2) of 1.0. The number of multiple scattering paths was set at six and applied to a cluster size of radius equal to 7.98 Å consisting of a total of 152 atoms. FEFF runs were repeated for Θ_D values ranging from 200 to 500 K at increments of 10 K. These data were then least-squares fit to the experimental data with one adjustable parameter, that being the relative occupancy of the Pr on the Ba- and Y-sites. A v_0 offset was systematically stepped through values ranging from ± 5 eV at a step-size of 0.25 eV to refine the value of E_0 , which had been arbitrarily assigned during refinement as the energy corresponding to the half height of the absorption step. The optimal value was determined by minimizing the χ^2 fitting parameter after which it was held fixed for the remainder of the analysis. Fitting was repeated for each combination of FEFF data as a function of Θ_D until, once again, χ^2 was minimized and a best fit was determined.

The temperature dependent magnetic susceptibility was measured in a SQUID susceptometer. The temperature sweeps were taken using applied magnetic fields of 2.0, 1.0, 0.1, 0.01, and 0.005 T. Except for the 0.005 T temperature sweep, data was taken while cooling the samples in field. In order to exclude pinning effects as a possible explanation for the suppression of any superconductivity, the 0.005 T temperature sweep was taken by first cooling the sample in zero field and then warming the sample in the applied field. The results are shown in Fig. 1, and indicate that the powder Pr sample is increasingly paramagnetic with decreasing temperature. A slight "kink" in the data near 12 K is consistent with observations of an antiferromagnetic ordering of the Pr sublattice which have been reported in numerous studies.^{10,11} The absence of any other features in the data is evidence for this material being a nonsuperconductor. The sensitivity of the system is such that a signal corresponding to as little as 0.05% bulk superconductivity would be detectable.

FIG. 2. Experimental $\text{Pr } L_{II}$ EXAFS after conversion to photoelectron wave vector space (k) with best fit data calculated using Y-site $\text{Pr } L_{II}$ FEFF data and Ba-site $\text{Pr } L_{II}$ FEFF data. See the text for discussion of calculated data. Least-squares fitting was performed using the relative fraction of site filling as the only adjustable parameter. The best fit reflects 100% occupation of Pr on the Y-sites.

The $\text{Pr } L_{II}$ EXAFS data was least-squares fit with FEFF data as described in Sec. II. The calculated best fit to the experimental EXAFS data are presented in Fig. 2. The best fit contains 0% Pr on the Ba-site. Again, the only adjustable parameter during fitting was the relative fraction of site occupation between the Y-site and the Ba-site. Figure 3 is a plot of the experimental $\text{Pr } L_{II}$ EXAFS with the Pr(Ba) -site L_{II} FEFF. Because the Pr(Ba) site L_{II} FEFF is nearly $\pi/2$ out of phase over a wide range of low- k values with respect to the Pr(Y) -site L_{II} FEFF (see Fig. 3), the least-squares fitting is acutely sensitive to even small amounts of Ba-site filling of Pr.

In Fig. 4 is plotted the χ^2 fitting parameter as a function of the percentage of Pr Ba-site filling. In these examples the percentage of Pr on the Ba-site was constrained to be a fixed percentage (1%–10%) and a least-squares best fit was calculated. In order to evaluate the sensitivity of these fitting analyses, an uncertainty limit of χ^2 values was defined by fitting the experimental mean \pm one standard deviation data with fit parameters fixed to those of the best fit. The standard

FIG. 3. Experimental $\text{Pr } L_{II}$ EXAFS after conversion to photoelectron wave vector space (k) with the Ba-site $\text{Pr } L_{II}$ FEFF data. Notice that the Pr(Ba) -site L_{II} FEFF is nearly $\pi/2$ out of phase over a wide range in k space.

FIG. 4. χ^2 fitting parameter as a function of the percentage of Pr Ba-site filling. In these examples the percentage of Pr on the Ba-site was constrained to be a fixed percentage and a least-squares best fit was calculated. An uncertainty limit of χ^2 values is defined by fitting the experimental mean \pm one standard deviation data with fit parameters fixed to those of the best fit. (See the text for details.)

deviation is defined by both the statistical uncertainty (merging several data sets) and by the uncertainty introduced to the data set by the procedural steps leading to and including the Fourier transform. Fits which result in χ^2 values that fall outside of these limits indicate that the fit parameters are untenable.

The results presented in Fig. 4 reflect fits where the local environment of the Pr ions on the Ba-sites are not allowed to relax. This is a direct result of limiting the number of adjustable parameters to the fractional site filling. When one allows an additional degree of freedom, specifically, relaxation of the local environment surrounding these sites, then the uncertainty limits of permissible χ^2 values double allowing for approximately 1% of Pr ions on Ba sites.

Several mechanisms have been argued to be responsible for the absence of superconductivity in PBCO and/or its non-metallic transport. These mechanisms include magnetic pair breaking,¹² hole filling,^{13,14} hybridization effects,¹⁵ or some combination thereof. The most widely accepted theories are those which incorporate hybridization effects, since there exists an abundance of experimental evidence for hybridization of Pr 4*f* orbitals with Cu-3*d*/O-2*p* valence states.¹⁶⁻¹⁸ Fehrenbacher and Rice (FR)¹⁹ and Liechtenstein and Mazin (LM)²⁰ have proposed similar theories which argue that this hybridization results in the formation of a band which is competitive in energy to the normal conduction band responsible for transport in the superconducting 123 materials. In the FR model, this band is described as being very narrow resulting in localized states, in contrast, the LM model argues that this band is dispersive and attributes the observed nonmetallic transport to disorder arising from substitution of Pr on the Ba-site. Our results indicate that disorder due to Pr substitution for Ba cannot account for the nonmetallic transport as suggested by LM, suggesting that perhaps some other mechanism is responsible for disorder in the Cu-O planes or, as FR have suggested the nonmetallic transport is due to localized states in the Cu-O planes coupled with disorder in the Cu-O chains.

Blackstead and Dow present another argument suggesting that, when prepared using conventional techniques for producing superconducting 123 materials, PBCO is non-superconducting due to the tendency of Pr to sit on the Ba-site, where it acts as a "pair-breaker," thereby destroying superconductivity.²¹ It is hard to reconcile Ba-site Pr with extensive XRD studies by Lowe-Ma and Vanderah which indicate that PBCO is strictly isostructural with the superconducting 123 structures, except for a slight shortening of the apical Cu-O bond.⁵ However, the sensitivity of these techniques preclude ruling out small (<5%) amounts of Pr substitution on the Ba site. The site selectivity and local structure sensitivity afforded by the EXAFS technique allows us to conclude that Pr does not substitute for Ba in this compound in amounts greater than 1%. This result precludes the possibility of Ba-site Pr as a source of superconductivity suppression in PBCO. In light of this new evidence, we conclude that Ba-site substitution of Pr is not a valid explanation for the absence of superconductivity in PBCO. This must be viewed as a serious challenge for the charge reservoir model.

This research was carried out, in part, at the National Synchrotron Light Source (Brookhaven National Laboratories, Upton, NY) which is sponsored by the U.S. Department of Energy.

Anisotropic thermal conductivity of c -axis aligned $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_x$ superconductor in high magnetic fields

S. C. Nakamae, J. Crow, J. Sarrao, and J. Schwartz

National High Magnetic Field Laboratory, Florida State University, Tallahassee, Florida 32310

The anomalous behavior of the thermal conductivity, κ , of high temperature superconductors (HTS) has been attributed to two conflicting theories (phonon domination and electron domination) since the discovery of HTS. Change in κ due to a magnetic field is a direct consequence of additional scattering processes between the phonons, the charge carriers, and the flux lines. The existing theories predict different scattering effects for the phonons and the electrons. Therefore, knowing magnetothermal conductivity can provide useful information for the nature of heat carriers in HTS and the understanding of the vortex dynamics. We have measured the in-plane thermal conductivity of a c -axis aligned $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_x$ superconductor in magnetic fields up to 17 T. The magnetic field was applied both parallel and perpendicular to the c axis and always perpendicular to the direction of heat flow. The results are compared to existing electronic and phononic models. It has been discovered that the electronic thermal conductivity, κ_e , calculated from the Wiedemann–Franz law, does not predict the measured behavior of the thermal conductivity. Rather, the phonon thermal conductivity, κ_{ph} , calculated from the extended BRT (Bardeen, Richayzen, and Tewordt) theory, reproduces the experimental results accurately. The anisotropy of the in-plane magnetothermal conductivity is also investigated. © 1998 American Institute of Physics. [S0021-8979(98)35811-9]

I. INTRODUCTION

Much work has been dedicated to the theoretical understanding of the thermal conductivity (κ) of HTS. Most of the existing theoretical models attribute the enhancement in κ below the transition temperature, T_c , to be of either the electronic origin^{1,2} or phononic origin.^{3–5} Furthermore, the crystal structure of HTS is highly anisotropic, causing anisotropy in κ . Consequently, the vortex structure in the mixed state of a layered HTS is strongly dependent on the field direction with respect to the c axis.⁶ The magnetothermal conductivity dependence on the field orientation reflects such vortex structure.

II. EXPERIMENT

A. Sample preparation and characterization

The crystals of $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_x$ were grown by a self-flux technique⁷ which produced shiny, micaceous crystals with a surface area of 1–3 mm². The sample used for the experiment was cut into a rectangular shape with dimensions 1.85 mm×1.7 mm×0.035 mm. SQUID and a Cantilever magnetometry were used to measure the magnetization and the transition temperature, T_c , of the sample. The Cantilever experiments were performed in the 20 T superconducting magnet (SCM). The upper critical field, H_{c2} was estimated from the magnetization data.

B. κ Measurements

The steady-state heat flow technique was used. The thermal conductivity, $\kappa(T)$, is calculated by

$$\kappa(T) = (Q \cdot l) / (A_x \cdot \Delta T), \quad (1)$$

where Q is the heat input for the sample (provided by a 100 Ω chip resistor), l ($=0.6 \pm 0.05$ mm) is the distance between the two thermocouples (Type E, 0.0005 in. diameter), A_x is the cross sectional area of the sample ($A_x = 1.7 \times 0.035 \pm 0.2$ mm²), and ΔT is the temperature difference between the two thermocouples. The schematic view of the experimental apparatus is presented in Fig. 1. The sample was mounted onto the Cu-heat sink with GE varnish with a thin sapphire plate in between for electrical insulation. A radiation shield can was placed around the sample area, then the sample space was evacuated to $<10^{-5}$ mbar. The sample temperature was monitored with a CERNOX temperature sensor. The sensor was placed on the Cu-heat sink underneath the base of the sample. The 20 T SCM was used for all thermal conductivity measurements. The field was applied both parallel and perpendicular to the c axis of the sample.

FIG. 1. Schematic view of the experimental apparatus.

III. THEORETICAL MODELS

A. κ_{ph} Models

Most of the theoretical models for the phonon thermal conductivity of superconductors available today are based on the BRT model⁸ which describes the κ_{ph} in zero magnetic field as

$$\kappa_{ph} = At^3 \int_0^\infty dx \frac{e^x x^4}{(e^x - 1)^2} (1 + \alpha t^4 x^4 + \beta t^2 x^2 + \delta t x + \gamma t x g(x, y))^{-1}, \quad (2)$$

where t , x , and y refer to reduced temperature (T/T_c), reduced phonon energy ($\hbar\omega/k_B T$), and the reduced energy gap ($\Delta/k_B T$), respectively. The coefficient A refers to the boundary scattering. The coefficients α , β , δ , and γ correspond to the relaxation rates for point-defects, sheetlike faults, dislocations and electron scattering. The exact form of $g(x, y)$ is found in Ref. 8.

In the presence of an applied magnetic field, H , the flux lines emerge, and thus an additional thermal resistance term appears, that is,

$$\Delta W(H, T) = \kappa^{-1}(H, T) - \kappa^{-1}(0, T) = \kappa_{ph-f}^{-1}(H, T). \quad (3)$$

For the in-field correction in the form of Eq. (2), we introduce an additional scattering term, $f(H/H_{c2})\gamma t x$, where $f(H/H_{c2})$ is a function of the reduced field. We have assumed that the relative area within the sample occupied by the flux lines is a function of the ratio between the applied field strength, H , and the upper critical field $H_{c2}(t)$. $f(H/H_{c2})$ must reach 1 (the maximum value) when the applied magnetic field exceeds $H_{c2}(t)$ of the sample at a given temperature. The flux lines are treated as line scattering sources. A similar analysis has been conducted by Mori *et al.* for the measurements on a $\text{Bi}_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_x$ polycrystalline sample.⁹ The simplified form of the $\Delta W(H, T)$ is

$$W(H, t) - W(0, t) = \left[At^3 \int_0^\infty dx \frac{e^x x^4}{(e^x - 1)^2} (f(H/H_{c2})\gamma' t x)^{-1} \right]^{-1}. \quad (4)$$

By integrating the above equation one obtains

$$\Delta W(H, t) = \frac{\gamma'}{At^2} f(H/H_{c2}). \quad (5)$$

Due to the highly anisotropic vortex structure of $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_x$, the form of $f(H/H_{c2})$ and the value of γ' are expected to be different for $H\parallel c$ and $H\perp c$ cases.

B. κ_e Models

In the electronic models, the main contribution to κ is believed to be the normal electrons in the Cu–O planes. Thus, we have used the Wiedemann–Franz law in conjunction with the experimental data on the microwave surface conductivity (σ) of a $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_x$ single crystal¹⁰ to estimate the electronic thermal conductivity in zero magnetic field. $\kappa_e = L\sigma T$, where L , Lorenz number, is taken to be $2.44 \times 10^{-8} \text{ W}\Omega/\text{K}^2$. Since the sample used in our experi-

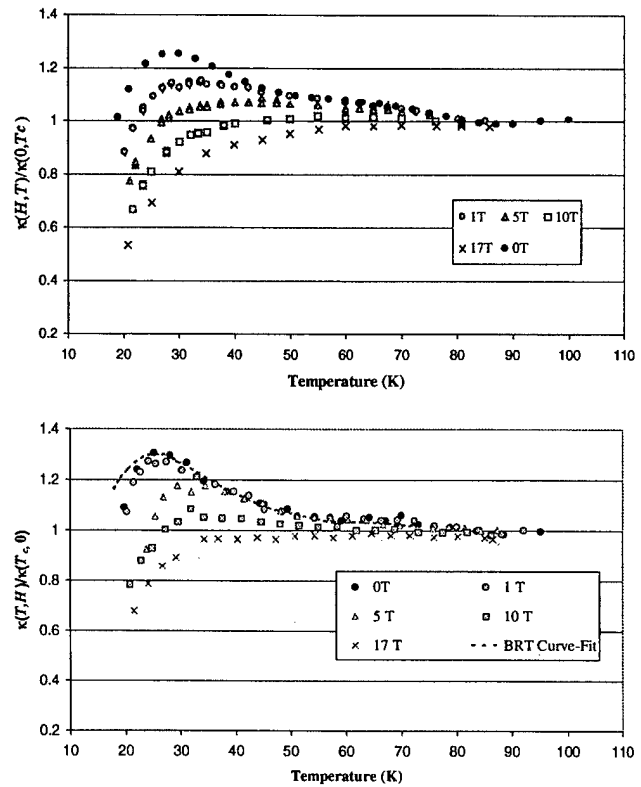

FIG. 2. (a) Normalized magnetothermal conductivity for $H\parallel c$ axis. (b) Normalized magnetothermal conductivity for $H\perp c$ axis.

ment contains more scattering sources than a single crystal, this value is considered to be the upper limit from the electronic contribution to the total thermal conductivity.

IV. RESULTS AND DISCUSSION

A. Magnetization results

From the magnetization measurements taken by SQUID and Cantilever magnetometry, the onset transition temperature is $85 \pm 1 \text{ K}$. From the Cantilever magnetization measurement results ($H\parallel c$), the upper critical field was observed to exceed 17 T immediately below T_c , and remains nearly constant for a wide temperature range for $75 \text{ K} > T > 35 \text{ K}$.¹¹ H_{c2} at $T=0 \text{ K}$ is estimated to be 80 T. For the procedure used to estimate H_{c2} , the readers should refer to Cho *et al.*¹¹ and Hao *et al.*¹²

B. κ Measurements and analysis

The normalized $\kappa(H, T)$ in applied magnetic fields up to 17 T for the two field orientations are presented in Figs. 2(a) and 2(b). The error analysis includes the heat leak through the gold wires, radiation loss between the sample and the radiation shield, and the voltage response change of the thermocouples in applied magnetic fields.¹³ The heat leak through the thermocouples was determined to be negligible compared to the other error sources.

First, the zero-field data is compared to the BRT model [see Fig. 2(b)]. The coefficients for the best fit are: $A = 57$, $\alpha = 44$, $\delta = 0.1$, $\delta = 2.0$ and $\gamma = 83$. The energy gap, $\Delta(0) = 8 \text{ meV}$, produces the correct $\kappa_{\max}(T)$ location,

FIG. 3. Estimated maximum κ_e from microwave surface conductivity data and Wiedemann–Franz law.

though this value is lower than most of the values found in the literature.¹⁴ Next, the data is compared to the electronic model (Wiedemann–Franz law). We have found that if the electronic contribution dominates, the peak in κ must occur at a temperature between 55 and 60 K as shown in Fig. 3. Some of the reported κ data of $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_x$ superconductors^{15,16} show κ_{max} around 60 K, supporting the normal electron scenario; however, our measured peak of 32 K is approximately 25 K lower. This discrepancy is most likely due to the impurity scattering, which effectively reduces the electronic thermal conductivity. For this reason, we believe that in our $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_x$ superconductor, the thermal conductivity is dominated by phonons. Therefore, we have only utilized the phonon theory in the following in-field κ analysis.

C. $\kappa_{\text{ph}}(H, T)$ Analysis

The thermal resistance change (ΔW) in magnetic fields (due to flux lines) are compared to the theoretical values calculated from Eq. (5). The results are shown in Figs. 4(a) and 4(b). The dotted lines represent the theoretical curves with $f(H/H_{c2}) = (H/H_{c2})^{1/2}$ for $H \parallel c$ measurements and $f(H/H_{c2}) = H/H_{c2}$ for $H \perp c$ measurements. $H_{c2}(0 \text{ K}) = 80 \text{ T}$ was used for both calculations. The H_{c2} value is taken to be nearly constant for a wide temperature range as discussed previously and temperature dependent for $t < 0.4$. The agreement between the experimental data and the theoretical curves is within 10% for all field values.

V. SUMMARY

We have shown that the in-plane thermal conductivity of c -axis aligned $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_x$ crystals is strongly dependent on the phonon contribution, rather than the electronic contribution. The field dependence of κ , $f(H/H_{c2})$ is determined to be $(H/H_{c2})^{1/2}$ when $H \parallel c$ axis and H/H_{c2} when $H \perp c$ axis. The different forms of $f(H/H_{c2})$ may be explained by further theoretical studies on the anisotropic vortex-phonon

FIG. 4. (a) Thermal resistance change for $H \parallel c$ axis. (b) Thermal resistance change for $H \perp c$ axis.

scattering effects (vortex spacing, normal metal coherence length, and flux pinning strength). Although the theoretical calculations and the experimental results are in agreement, we have not considered the κ_e contribution. Therefore, the inclusion of κ_e to the data analysis may improve the theoretical model especially in the lower field range.

Superconductivity in the new quaternary ruthenium borocarbide Y–Ru–B–C system

Y. Y. Hsu, H. C. Chiang, and H. C. Ku^{a)}

Department of Physics, National Tsing Hua University, Hsinchu, Taiwan 300, Republic of China

Two new quaternary borocarbide phases were discovered in the Y–Ru–B–C system: the (1111) YRuBC phase of the LuNiBC-type structure with tetragonal lattice parameters $a = 3.625\text{--}3.630\text{ \AA}$ and $c = 7.775\text{--}7.874\text{ \AA}$, and the (1221) YRu₂B₂C phase of the LuNi₂B₂C-type structure with tetragonal lattice parameters $a = 3.742\text{--}3.787\text{ \AA}$ and $c = 10.278\text{--}10.453\text{ \AA}$. Bulk superconductivity of 9.7 K was observed from transport and magnetic measurements for the annealed YRu₂B₂C sample with a short Ru–Ru bond length $d(\text{Ru–Ru}) = \sqrt{2} a/2 = 2.646\text{ \AA}$.

© 1998 American Institute of Physics. [S0021-8979(98)19211-3]

Superconductors with relatively high T_c up to 23 K have been reported in the quaternary borocarbides RT₂B₂C ($R = \text{Sc, Y, Th, U, or a rare earth; } T = \text{Ni, Pd, or Pt}$).^{1–13} The superconducting phases have been identified to be the LuNi₂B₂C-type (1221) body-centered tetragonal structure with space group $I4/mmm$. The structure is a three-dimensionally connected framework with LuC layers alternated with Ni₂B₂ layers where Ni is tetragonally coordinated by four boron atoms.⁴ Because of the great potential to find high T_c superconductors in this structure and other related structures, we investigate the Y–Ru–B–C system. In this article we report the discovery of two new quaternary borocarbides in the Y–Ru–B–C system. One is a high T_c compound YRu₂B₂C isostructural to LuNi₂B₂C.

All YRu_mB_mC ($m = 1, 2, 3, 4$) samples were prepared from high-purity elements (Y: 99.9%, Pd: 99.95%, B: 99.9995%, and C: 99.995%) with stoichiometric starting composition 1: m : m :1 ($m = 1\text{--}4$) under an argon atmosphere in a Zr-gettered arc furnace. The starting ingredients were slowly arc melted several times in order to ensure negligible weight loss and sample homogeneity. For annealing, the sample was wrapped in the Ta foil and sealed in a thick-wall (2 mm) quartz tube under Ar atmosphere, then annealed at 1200–1400 °C for one day. The crystallographic data were obtained with a Rigaku Rotaflex rotating anode x-ray diffractometer using Cu K_α radiation with a scanning rate of 1° in 2θ per minute. A Lazy Pulverix-PC program was employed for phase identification, lattice parameter calculation, and intensity calculation.

The magnetic susceptibility measurements were made with a μ -metal shielded Quantum Design MPMS₂ superconducting quantum interference device (SQUID) magnetometer down to 2 K in 10 G low magnetic field. The transport resistance data were obtained using the standard four-probe method with an ac (16 Hz) excitation current of 10 mA (rms) in the sample space chamber of the MPMS₂ down to 2 K.

For the as-melted YRuBC sample, powder x-ray diffraction data show a multiphase pattern with ~40% of the new LuNiBC-type (1111) phase (tetragonal lattice parameters $a = 3.635\text{ \AA}$, $c = 7.874\text{ \AA}$, and a unit volume $V = 104.0\text{ \AA}^3$),⁴

~40% of new LuNi₂B₂C-type (1221) phase (tetragonal $a = 3.787\text{ \AA}$, $c = 10.318\text{ \AA}$, and $V = 148.0\text{ \AA}^3$),⁴ and ~20% of unidentified impurity phases. Superconducting transition around 4 K was observed but with a very small (<1%) zero-field-cooled (ZFC) diamagnetic shielding signal of 9×10^{-6} emu (g G) at 2 K. This superconducting signal disappeared after the sample was annealed at 1200 °C for one day. The x-ray pattern for annealed sample indicates that after annealing, both the (1111) phase ($a = 3.620\text{ \AA}$, $c = 7.775\text{ \AA}$ and $V = 101.9\text{ \AA}^3$) and the (1221) phase ($a = 3.787\text{ \AA}$, $c = 10.314\text{ \AA}$, and $V = 147.9\text{ \AA}^3$) have a slightly reduced volume due to thermal diffusion and possible boron/carbon loss during annealing.

For the as-melted YRu₂B₂C sample, the powder x-ray diffraction data also show a multiphase pattern with ~70% of the new tetragonal (1221) phase ($a = 3.780\text{ \AA}$, $c = 10.278\text{ \AA}$, and $V = 146.9\text{ \AA}^3$), no new (1111) phase, and ~30% of unidentified impurity phases. No superconductivity was observed down to 2 K for the as-melted YRu₂B₂C sample. It is noted that the new (1221) phase unit cell volume of 146.9 \AA^3 in the as-melted YRu₂B₂C sample is smaller than $147.9\text{--}148.0\text{ \AA}^3$ observed from the multiphase YRuBC sample.

In order to enhance the effect of thermal diffusion and sample homogeneity through heat treatment, the YRu₂B₂C sample was annealed at a very high temperature of 1400 °C for one day in a thick-wall (2 mm) quartz tube. After the high temperature annealing, the x-ray diffraction pattern in Fig. 1 shows no improvement of the new (1221) phase concentration (~70%) but with a smaller unit cell volume ($a = 3.742\text{ \AA}$, $c = 10.453\text{ \AA}$, and $V = 146.4\text{ \AA}^3$). The calculated intensity using the atomic positions of the LuNi₂B₂C-type (1221) phase⁴ in YRu₂B₂C is shown in Fig. 2 for comparison. All unidentified impurity phases in as-melted sample disappeared after annealing, with the emergence of a new impurity phase of ternary YRu₄B₄ with tetragonal lattice parameter $a = 7.45\text{ \AA}$, $c = 14.99\text{ \AA}$.¹⁴ The variation of lattice parameters and unit cell volume for the new (1221) phase indicates that there is a homogeneity range YRu_{2–x}B_{2–y}C_{1–z} for the phase in the Y–Ru–B–C phase diagram.

The low temperature relative electrical resistance

^{a)}Electronic mail: hcku@phys.nthu.edu.tw

FIG. 1. Powder x-ray diffraction patterns of annealed $\text{YRu}_2\text{B}_2\text{C}$ sample. The new $\text{LuNi}_2\text{B}_2\text{C}$ -type (1221) tetragonal phase lines are indexed ($a=3.74 \text{ \AA}$, $c=10.453 \text{ \AA}$). Major impurity is the ternary tetragonal YRu_4B_4 (marked by (4), with $a=7.45 \text{ \AA}$, $c=14.99 \text{ \AA}$).

$R(T)/R(300 \text{ K})$ for the annealed $\text{YRu}_2\text{B}_2\text{C}$ sample is shown in Fig. 3. A sharp superconductivity transition with zero resistance $T_c(\text{zero})$ was observed at 9.6 K and a superconducting onset (1%) $T_c(\text{onset})$ around 10 K. The resistance decreases monotonically with decreasing temperature as expected for a metallic compound, with a large extrapolated residual resistance ratio $R(0)/R(300 \text{ K})$ of 0.73 due to the impurity scattering of the ternary YRu_4B_4 phase. Since the YRu_4B_4 impurity phase is a low T_c superconductor of 1.4 K¹⁴ and other ternary impurities YRuB_2 ($T_c=7.8 \text{ K}$), YRuB_4 ($T_c=1.4 \text{ K}$), and YRu_3B_2 (no T_c down to 1.2 K)^{15,16} were not observed, the new 10 K superconducting phase with narrow transition width of 0.4 K is probably due to the new (1221) phase having a shorter Ru-Ru bond length $d(\text{Ru-Ru})=\sqrt{2} a/2=2.646 \text{ \AA}$ as compared with $d=2.673 \text{ \AA}$ for the as-melted sample. In the isostructural non-magnetic $\text{RNi}_2\text{B}_2\text{C}$ system, similar T_c variation versus Ni-Ni bond length was observed with T_c of 17 K for $d(\text{Ni-Ni})=2.53 \text{ \AA}$, 4 K for 2.65 \AA , and below 1 K for 2.68 \AA .⁹ For the nonmagnetic $\text{RPd}_2\text{B}_2\text{C}$ system, T_c of 23 K for

FIG. 3. Low temperature relative resistance $R(T)/R(300 \text{ K})$ of annealed $\text{YRu}_2\text{B}_2\text{C}$ sample, with $T_c(\text{onset})$ at 10 K, $T_c(\text{mid})$ at 9.7 K, and $T_c(\text{zero})$ at 9.6 K.

Pd-Pd bond length $d(\text{Pd-Pd})=2.53 \text{ \AA}$ and 2 K for $d=2.80 \text{ \AA}$ were observed.¹¹

The bulk nature of superconductivity can be checked through the magnetic measurement. The low temperature mass magnetic susceptibility $\chi_g(T)$ of the same sample is shown in Fig. 4 for both the zero-field-cooled (ZFC) and field-cooled (FC) measurements in a low applied field of 10 G. A diamagnetic superconducting transition signal was observed at 9.7 K, a value equal to the midpoint transition $T_c(\text{mid})$ of 9.7 K from the transport measurement. A large ZFC shielding signal of $-1.9 \times 10^{-2} \text{ emu/(g G)}$ at 2 K for the bulk sample indicates the bulk superconducting effect (using the calculated x-ray density of 7.12 g/cm^3). For the powder sample (200 mesh), smaller ZFC signal of $-3.4 \times 10^{-3} \text{ emu/(g G)}$ at 2 K was observed in Fig. 5, due to the multiphase nature of the sample. A large FC signal of $-2.0 \times 10^{-3} \text{ emu/(g G)}$ at 2 K for powder sample was observed as compared with smaller FC signal of $-2.9 \times 10^{-4} \text{ emu/(g G)}$ at 2 K for bulk sample to de-pinning in the powdering process.

FIG. 2. Calculated intensity of $\text{LuNi}_2\text{B}_2\text{C}$ -type (1221) tetragonal phase in $\text{YRu}_2\text{B}_2\text{C}$.

FIG. 4. Low temperature mass magnetic susceptibility χ_g of annealed $\text{YRu}_2\text{B}_2\text{C}$ bulk sample in field-cooled (FC) and in zero-field-cooled (ZFC) modes. The superconducting transition T_c at 9.7 K was observed.

FIG. 5. Low temperature mass magnetic susceptibility χ_g of annealed $\text{YRu}_2\text{B}_2\text{C}$ powder sample (200 mesh).

To check the impurity superconductivity, two more samples were prepared. For the $\text{YRu}_3\text{B}_3\text{C}$ sample, the x-ray data showed mostly the YRu_4B_4 phase ($\sim 80\%$) for both as-melted and annealed samples. Two small superconducting transitions around 8 K ZFC diamagnetic signal of 1×10^{-5} emu/(g G) at 2 K and 4 K [ZFC diamagnetic signal of 2×10^{-4} emu/(g G) at 2 K] were observed. Since the orthorhombic ternary YRuB_2 phase has a T_c of 7.8 K,¹⁶ the 8 K transition is probably from the impurity YRuB_2 phase or the new $\text{YRu}_2\text{B}_2\text{C}$ phase. For the $\text{YRu}_4\text{B}_4\text{C}$ sample, the x-ray data show mostly the YRu_4B_4 phase ($>90\%$) for both as-melted and annealed samples. A small superconducting transition around 3 K was observed with the ZFC diamagnetic signal of 5×10^{-5} emu/(g G) at 2 K.

In conclusion, two new quaternary borocarbide phases were discovered in the Y–Ru–B–C system: the (1221) $\text{YRu}_2\text{B}_2\text{C}$ phase of the $\text{LuNi}_2\text{B}_2\text{C}$ -type structure and the (1111) YRuBC phase of the LuNiBC -type structure. Bulk

superconductivity of 9.7 K was observed for the annealed $\text{YRu}_2\text{B}_2\text{C}$ sample with the shortest Ru–Ru bond length. Impurity superconductivity of 3–4 K was also observed in the Y–Ru–B–C system.

The Co-rich system (Co_{1-x}Cu_x)Co₂S₄ ($x=0-1$) and the Cu-rich system Cu[Cu_xCo_{2-x}]S₄ ($x=0-0.5$) were synthesized, and x-ray diffraction, magnetic susceptibility χ , and electrical resistivity ρ were studied. Curie-Weiss-type susceptibility with an antiferromagnetic structure with $T_N \approx 20$ K was observed for $x=0.3-1$ in the Co-rich system. This type of antiferromagnetism showed a similar behavior with those obtained previously for an antiferromagnetic and superconductive Cu-rich system. ρ showed a typical metallic-type temperature dependence and is proportional to T for the Co-rich system with antiferromagnetism and showed quadratic temperature dependence with the cross over temperature of 75 K for the Cu-rich system with antiferromagnetism and superconductivity. A 3d hole-electron correlation was observed to be concerned with Cu-S superconductivity. © 1998 American Institute of Physics. [S0021-8979(98)16811-1]

I. INTRODUCTION

In copper oxide high-temperature superconductors (HTS), the 3d hole carrier in the bonding orbits ($3d_{\gamma}-p_{\sigma}$) of the two-dimensional copper oxygen CuO₂ plane is responsible for the superconductivity, and the anisotropic properties result in complicated properties and physics. Among the various theoretical aspects for the origin of the superconductivity, the electron correlation is believed to take an important role.

From various exploring works on the copper sulfide superconductors by the present authors,^{1,2} the Cu-rich system Cu_{1+x}Co_{2-x}S₄ ($x=0-0.5$) was found to show an antiferromagnetic behavior on magnetic susceptibility with the Néel temperature $T_N \approx 20$ K ($x=0-0.5$) and to show superconductivity below $T_c = 4.0$ K depending on $x=0-0.5$. In the system, Cu-S bonding orbits are formed resulting in p -type conductivity like the case of Cu-O bonding in HTS. From a NMR study³ on Cu_{1.5}Co_{1.5}S₄ an enhancement of $(T_1T)^{-1}$ at T_N was observed.

In this work, a Co-rich cubic spinel system (Co_{1-x}Cu_x)Co₂S₄ ($x=0-1$) was developed and the crystallography, magnetic susceptibility, and electrical resistivity were studied to extend the understanding of the antiferromagnetism and superconductivity in the Cu-rich system.

II. EXPERIMENTS

The polycrystalline samples of the Co-rich system (Co_{1-x}Cu_x)Co₂S₄ ($x=0-1$) and the Cu-rich system Cu_{1+x}Co_{2-x}S₄ ($x=0-0.5$) were synthesized by a standard vacuum sealed quartz ampoule method. Starting materials of CuS, Co, and S were used, and the ampoule was heated at 500–800 °C for 20 h depending on the Cu composition. The system was synthesized well only when ~ 2 wt % moisture

was charged as a carrier gas. X-ray diffraction analysis showed these samples to be single phase and the Rietveld analysis showed that the whole system is a normal cubic spinel with the ionic distributions of (Co_{1-x}Cu_x)[Co₂]S₄ and Cu[Cu_xCo_{2-x}]S₄.

The lattice constant a and the u parameter, anion position, are shown in Fig. 1 over the entire range of Cu and Co concentrations, where starting from Co₃S₄ ($x=0$), $a(x)$ increases nonlinearly as Cu concentration increases, while the u parameter changes linearly within the experimental error and obeys the Begards law. The Cu locates in the tetrahedral site in the Co-rich system, and goes to the octahedral site also in the Cu-rich system.

The magnetic susceptibility of the Co-rich system (Co_{1-x}Cu_x)Co₂S₄ was measured above 2.8 K using a vibrating sample magnetometer. The low Cu doping range ($x=0-0.2$) basically showed a Pauli paramagnetism with a small temperature dependence. While Curie-Weiss-type susceptibility χ was observed for $x=0.3-1$, and an antiferromagnetic structure was observed below $T \approx 20$ K, which we assumed to be the Néel temperature. This antiferromagnetism continues to the superconductive Cu-rich system, which was observed previously.^{2,3} This antiferromagnetism is being studied by Sugita *et al.*⁴ of our working group using the NMR technique, and the $(T_1T)^{-1}$ enhancement was observed at ~ 55 and ~ 20 K for $x=0$ and 0.3, respectively, corresponding to the weak antiferromagnetic Néel temperature T_N .

The electrical resistivity ρ of the two systems was also measured above 10 K on the sintered and shaped bar samples by the conventional four-probe ac technique at 10 Hz using a helium refrigerator, and the results are shown in Figs. 2 and 3 for the Co- and Cu-rich systems, respectively. In the case of the Co-rich system in Fig. 2, ρ is, typically, metalliclike and is proportional to T except near Co₃S₄ ($x=0-0.15$). ρ of Co₃S₄ decreases rapidly below ~ 150 K and has a convex-

FIG. 1. The lattice constant a and u parameters of the Co and Cu systems $\text{Cu}_x\text{Co}_{3-x}\text{S}_4$ with cubic spinel structure.

FIG. 3. The resistivity measured at ac (10 Hz) of the Cu-rich system $\text{Cu}[\text{Cu}_x\text{Co}_{2-x}]\text{S}_4$ ($x=0-0.5$) in the normal state.

type change. A small but broad structure was observed on the curve below ~ 60 K. It was also observed that the ρ of low-level Cu doping ($x \approx 0.05$) increases abruptly at low temperature, and a resistivity minimum appears at about 55 K, which corresponds to the T_N of Co_3S_4 . This resistivity minimum becomes less pronounced as the Cu concentration increases and disappears for the high-density Cu lattice $x > 0.2$.

ρ of the Cu-rich system with superconductivity showed a very large temperature dependence even in the normal state as is shown in Fig. 3. ρ of CuCo_2S_4 ($x=0$) is, typically, metalliclike and is proportional to T , however, ρ for $x=0.3, 0.4$, and 0.5 rapidly decreases as the temperature is lowered with a convex-type temperature dependence. The convexity is enhanced as x increases to 0.5 , and it becomes

superconductive in low temperature at $T_c=4.0$ K for $\text{Cu}_{1.5}\text{Co}_{1.5}\text{S}_4$ ($x=0.5$).

The self-consistent renormalization spin fluctuation theory⁵ and Fermi-liquid theory with a strong electron correlation⁶ suggest that the resistivity has a temperature dependence of

FIG. 2. The resistivity measured at ac (10 Hz) of the Co-rich system $(\text{Co}_{1-x}\text{Cu}_x)\text{Co}_2\text{S}_4$ ($x=0-1$) in the normal state.

FIG. 4. The $\log(\rho - \rho_0)$ vs $\log T$ plots for the square law fitting in the normal state of the Cu-rich superconductive samples.

TABLE I. The quadratic term coefficient A and related parameters with typical heavy Fermion Kondo compounds and normal metals.

	Crystal structure	T_N (K)	T_c (K)	A ($\mu\Omega$ cm/K ²)	γ (mJ/mol K ²)	m^*/m
Cu _{1.5} Co _{1.5} S ₄	Cubic spinel	20	4.0 ^a	1.51~9.1
UPt ₃	Hexagonal	17	0.49–0.52	1.6($\perp c$), 0.7($\parallel c$)	450	180–230
URu ₂ Si ₂	Tetragonal	17.5	1.2	0.119	180	140
Pd	fcc	10 ⁻⁵	9.4	...
Ag	fcc	10 ⁻⁷	0.6	...

^aOur updated value is extended to 4.9 K.

$$\rho(T) = \rho_0 + AT^2/(T + T_l) = \rho_0 + A_l T^2$$

$$\text{for } T \ll T_l$$

$$= \rho_0 + A_h T \text{ for } T \gg T_l.$$

The electrical resistivity is, thus, expected to have a quadratic-type temperature dependence below the transformation temperature T_l and the linear temperature dependence above T_l .

ρ for the three samples of Cu_{1.5}Co_{1.5}S₄, synthesized at 500, 680, and 800 °C, are plotted in Fig. 4 to see the temperature dependence in terms of $\rho(T) = \rho_0 + AT^n$. It is shown that the resistivity fits relatively well with the quadratic term $n=2$ at low temperature and fits with a linear temperature term $n=1$ above the crossover temperature T_l .

The coefficient A is obtained from the quadratic term in Fig. 4 to be 1.5–9.1 $\mu\Omega$ cm/K² over all samples, and the crossover temperature T_l , which should correspond to the Debye temperature, to be ~ 75 K, respectively. It is interesting to compare A with those known as the typical Kondo compounds UPt₃ (0.7 $\parallel c$, $\mu\Omega$ cm/K²) (Ref. 7) and URu₂Si₂ (0.119 $\mu\Omega$ cm/K²) (Ref. 8) and those of typical metals Ag (10⁻⁷ $\mu\Omega$ cm/K²) and Pd (10⁻⁵ $\mu\Omega$ cm/K²). These values of A are listed in Table I with the Sommerfeld parameter γ and the effective mass ratio m^*/m . It is shown that the resistivity of Cu_{1.5}Co_{1.5}S₄ has a large quadratic term coefficient A comparable with those of the Kondo compounds known as the typical heavy Fermion.

III. DISCUSSION

The susceptibility shows an antiferromagnetic structure with $T_N \approx 20$ K for the Co-rich system ($x=0.3-1$), and the electrical resistivity rapidly changes from a quadratic-type to a metallic one by Cu doping ($x=0-0.2$), as is seen in Fig. 2. Cu doping also causes the resistivity minimum at ~ 55 K, which corresponds to the Néel temperature of weak antiferromagnetic Co₃S₄ ($x=0$).⁴ Thus, ρ seems to be sensitive with the spin state in the k space.

The coefficient A of the quadratic term given in Table I is proportional to the square of the Sommerfeld parameter γ .² The present result shows that A has the same order of

magnitude as the typical heavy Fermion compounds. This suggests that the superconductivity of the Cu-rich system is related to the large value of A , reflecting large γ , large effective mass m^* , a high density of state at the Fermi level, and a strong $3d$ hole correlation.

In the case of the TI-221 HTS Cu–O system,⁹ the resistivity shows the T linear type for the superconductive samples and shows the quadratic type for the nonsuperconductive sample depending on the oxygen concentrations. In contrast to this work, the present result for the Cu–S spinel system shows that the quadratic term is observed only for the Cu-rich superconductive compositions, but the linear term only for the Co-rich nonsuperconductor ($x=0.3-1$). We, thus, conclude that the present Cu–S system presents a typical example for the superconductivity concerned with the $3d$ hole electron correlation. Understanding of the spin correlation of antiferromagnetism with superconductivity is, however, still left to study in future work.

Plausible d -wave cuprate superconductivity: Muon-spin-relaxation studies of $\text{RBa}_2\text{Cu}_3\text{O}_{7-\delta}$ vortex states

C. Boekema,^{a)} E. J. Ruiz, Z. C. Pobre, S. R. Punjabi, F. Kong, and O. Vera

The rare-earth (R) magnetism and grain-size dependencies of magnetic field distributions in $\text{RBa}_2\text{Cu}_3\text{O}_{7-\delta}$ (RBCO) vortex states have been studied. A maximum-entropy technique has been applied to transverse field muon-spin-relaxation data of several polycrystalline cuprate superconductors. The main vortex signals for $R=\text{Er}$, Gd , and Ho reveal signs of two peaks in the field distribution below the applied field ($B_{\text{ext}}=1$ kOe) as predicted for d -wave superconductivity. For the RBCO ($R=\text{Er}$, Gd , Ho , Eu , Y) vortex states, we have confirmed low-field tails in the field distributions well below B_{ext} . The low-field tail may be caused by magnetic frustration in the vortex state or possible CuO -chain superconductivity below 25 K. Any interpretation of these (magnetic) vortex anomalies should comprise unconventional non-Bardeen-Cooper-Schrieffer-like fundamental properties of the cuprate vortex states. © 1998 American Institute of Physics. [S0021-8979(98)19311-8]

I. INTRODUCTION AND D -WAVE VORTEX STATES

Significant contributions toward understanding the vortex states of the cuprate superconductors are being made by magnetic resonance applications. Muon-spin-relaxation (μSR) studies of these mixed magnetic and superconducting states may provide direct answers to critical questions such as whether the magnetic field distribution shows the two distinct peaks in the main vortex part, as predicted by the Ginzburg-Landau (GL) theory.¹ The μSR studies² have indicated deviations from typical type II Abrikosov vortex behavior. Studying the interplay of magnetism and superconductivity can lead to a better understanding of the physical origin of cuprate superconductivity.

Although there is no general agreement on the fundamental mechanism of cuprate superconductivity, an excellent approach is the phenomenological (GL) theory. Application of the GL theory to *conventional* superconductors has revealed its ability to predict most of their vortex properties. The GL theory is based upon general concepts related to symmetries of the vortex system under investigation. With this approach, one adopts the basic assumption that "Cooper" pairs exist. Cooper pairs can be described by an "order parameter" $Y(r)$, and the "super-electron" density is given by $|Y(r)|^2$.

The GL theory (appropriate for d -wave symmetry) involves both d -wave and induced s -wave order parameters. Assuming type-II superconductivity, the magnetic field distribution in the d -wave vortex state can be predicted.¹ Characteristic of a d -wave superconductor, an oblique vortex lattice has been found; two distinct Van Hove-like singularities lead to the prediction of two distinct peaks in the magnetic field distribution of the vortex state.^{1(c),1(d)}

II. μSR RESEARCH AND DATA ANALYSIS

In our μSR research, we have investigated² the vortex states of ceramic cuprate superconducting $\text{RBa}_2\text{Cu}_3\text{O}_{7-\delta}$ RBCO samples which have T_c 's ranging from 66 to 94 K. R signifies a rare-earth (RE) element such as Er , Gd , Ho , Eu , or (the RE-like element) Y . The polycrystalline cuprate samples are high-quality single-phase ceramics prepared at Los Alamos National Laboratory. The samples were field cooled in 1 kOe transverse fields.

The μSR technique is similar to nuclear magnetic resonance (NMR) and the Mössbauer effect. In the transverse-field (TF) mode, the Larmor precession of the muon spin is proportional to the magnetic field at the muon-probe site. In μSR studies of magnetic field distributions, the recorded muon-decay time histograms are analyzed by the maximum-entropy (ME) method. Spectral densities found in the ME transform reflect directly the field distribution.^{2(a),3} ME has the advantage of producing in the frequency transform only structure for which sufficient statistical evidence in the time series is present. We analyze TF μSR data using an ME method based on the Burg algorithm for minimizing noise in the equation

$$S_i = \sum c_k S_{i-k} + n_i,$$

where S_i is the muon-spin polarization at time i , and n_i the assumed white noise term. The autoregressive coefficients c_k ($k=1,\dots,p$) are determined from the data, where p is the order of the model description. To maximize the ME- μSR signal-to-noise ratio, S_i can be weighted before ME transformation by an exponential or Gaussian filter function with a filter time T_f . Most ME analyses are performed using a Gaussian filter function, as μSR signals with Gaussian relaxation are expected below T_c . This reduces noise, but causes an expected $1/T_f$ broadening effect in the ME transformation.

^{a)}Electronic mail: boekemac@aol.com

FIG. 1. ME transforms for ErBCO μ SR time-histogram data recorded at 1 kOe, and 4.5 K (●) and 5.5 K (○). Gaussian filtering ($T_f=0.7 \mu$ s) and background correction have been done. The falloff at 4.5 K (seen near 700 Oe) starts to disappear above 5 K; consequently, the main vortex and GB signals increase in intensity. The low-field tail stretches out to zero field; compare with the YBCO vortex (Fig. 3) result.

III. MAIN RESULTS and DISCUSSION

ME- μ SR analysis has shown the following features for RBCO vortex states: (0) A major vortex signal below the applied field of $B_{\text{ext}}=1$ kOe (see Fig. 1); (1) signs of the predicted twin peaks in the main vortex signal (suggesting d -wave symmetry, see Fig. 2); (2) a falloff below the applied field, when R is magnetic, and near 4 K; (3) a low-field tail below 25 K; (4) a peak near the applied field.

Likely, the major part corresponds to the vortex structure as observed by neutron scattering.⁴ Deviations 2 and 3 (see Fig. 1) indicate an unusual interplay between magnetism and superconductivity for the RBCO vortex states. As

FIG. 2. ME transforms for GdBCO μ SR time-histogram data recorded at 1 kOe, and 4.3, 6.5, and 15 K. Gaussian filtering ($T_f=4.4 \mu$ s) and background correction have been done. The signals near the applied field are due to grain boundaries. A twin-peak signature can be seen developing below 10 K.

FIG. 3. ME transform for YBCO (large $70 \mu\text{m}$ grains) μ SR time-histogram data recorded at 1 kOe, and 3.2 K. Gaussian filtering ($T_f=1 \mu$ s) and background correction have been done. The low-field tail can clearly be seen. Below 600 Oe, the spectral density in the vortex field distribution is zero; compare with the ErBCO vortex (Fig. 1) results.

predicted^{1(c),1(d)} for d -wave superconductivity, the main vortex signals for $R=\text{Ho}$, Gd , and Er reveal signs of two peaks in the field distribution below the applied field below 10 K. Above 10 K, this signature disappears and is not present above 25 K. In Fig. 2, we show ME spectral density transforms for GdBCO (using 4.4μ Gaussian filtering) indicating signs of twin peaks, as predicted by the d -wave GL theory. Near 4 K, the main vortex signal with these peaks superimposed shifts to lower fields, as the magnitude of the R magnetic moment increases.

For the RBCO ($R=\text{Er}$, Gd , Ho , Eu , Y) vortex states, we also have observed low-field tails in the field distributions well below B_{ext} . The low-field tail is only present below 25 K. This tail is *not* seen in the *real* parts of the Fourier transforms (FT) because of sinc-wiggle and truncation effects.^{2(a),3} (The real FT part approximates the field distribution.) These non-Abrikosov tails in the YBCO vortex field distributions are slightly grain-size dependent.^{2(d)} In Fig. 3, a ME transform is shown for a YBCO sample having a large grain size ($\sim 70 \mu\text{m}$), with μ SR data recorded at 1 kOe and 3.2 K. The spectral density behavior and thus the field distribution at the muon-probe sites⁵ confirm the low-field tail (0.60–0.75 kOe) for RBCO vortex states with a nonmagnetic R ion.

The R -layer magnetism spreads the tail out to lower fields; for $R=\text{Er}$, this tail reaches as low as zero field (see Fig. 1). We speculate that the low-field tail is caused by magnetic frustration^{2(b)} in the vortex state or possible CuO chain superconductivity below 30 K. The latter possibility has been suggested by NMR evidence.⁶ Note also that the muon-probe sites are very near to the CuO chain layers.⁵ Furthermore, this tail does *not* show up in the vortex field distributions of the cuprates Bi2212 and Tl2223 (at 5 kOe).^{2(b)}

In ME transforms using an exponential filter time $T_f=4.4 \mu\text{s}$, the peak near the applied field clearly stands out, and its position is slightly T -dependent. This grain-boundary

(GB) peak originates from grain boundaries or other nonsuperconducting regions, where disorder in the chain layers exists at the atomic level. This particular μ SR signal is *not* seen in the vortex states of $\text{Pb}_{0.9}\text{In}_{0.1}$,^{2(c)} a prime example of a classical Bardeen–Cooper–Schrieffer (BCS) superconductor.

In Table I, we summarize the observed twin splittings and compare with the GL predictions. The ME estimates of the observed twin-peak splittings are about 2.5 times larger than predicted. Because of the large overlap of the GB peak and the main vortex signal for nonmagnetic R 's, no precise determination has been made in such cases, although weak indications do exist. To clearly resolve the predicted splitting, a μ SR time window of at least 5 μ s is required to see the “beat” pattern in the time histogram created by these twin peaks. Our μ SR time window is about 7.2 μ s (such a relative short time is the main reason a Fourier analysis will *fail* to show this twin-peak signature).

The main vortex signal is shifted from the GB signal as a result of the R -layer magnetism. However, this magnetic effect may also have enhanced the splitting. The *alternative*, that the second peak is caused by R magnetism, is less likely: the observed splitting appears to be independent of the R magnetic moment. In contrast, the falloff and low-field tail shift to lower fields with increasing R moment.² Note, R -layer magnetism in RBCO already has shown anomalous behavior: for instance, unusual high magnetic ordering temperatures (near 2 K for $R=\text{Er}$ and Gd).

The fact that the observed twin splitting is temperature dependent (see Fig. 2 and Table I) substantiates the likely existence of the twin-peak signature below 10 K. Preliminary ME transforms of *simulation* μ SR data using the twin-splitting prediction value^{1(d)} reveal a twin splitting enlarged by only 25% (see also Table I). Compared to the much larger observed splitting, this is not unexpected, and perhaps acceptable: namely, the cuprate vortex state is *not* typical type II (as is assumed for the d -wave vortex state).

IV. CONCLUSION

Maximum entropy is a sensitive method for examining μ SR vortex spectra. Not only has ME- μ SR analysis indicated magnetic anomalies in the vortex state, but is allowing for the current analysis of d -wave symmetry in cuprate superconductivity. Our ME- μ SR studies, especially the confirmation of the low-field vortex tail, indicate that cuprate superconductivity differs substantially from type II BCS-like behavior. Unusual characteristics like a falloff and low-field tail in the vortex field distributions do not conform to Abrikosov features of type II superconductors. The behavior of the cuprate vortex state indicates plausible d -wave symmetry, which could be an essential key ingredient in the understanding of the cuprate superconductivity mechanism.

Flux patterns of multifilamentary Ag-sheathed $(\text{Pb,Bi})_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_{10+\delta}$ tapes comprising 19 filaments are visualized by means of magneto-optic imaging. In low fields, the shielding currents are seen to flow mainly in the outermost filaments. With increasing external magnetic field, the inner filaments also contribute to the current flow. To compare the local flux distribution with the integral magnetization values, magnetization loops are measured by a SQUID magnetometer on the same sample following the fields used in the magneto-optic imaging (± 120 mT) and covering fields up to ± 5 T at various temperatures. The magnetization loops also reveal that the multifilamentary tapes show the anomalous position of the central peak, but always less pronounced than in monofilamentary tapes. © 1998 American Institute of Physics. [S0021-8979(98)53111-8]

The Ag-sheathed multifilamentary tapes of $(\text{Pb,Bi})_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_{10+\delta}$ (Bi-2223) are an important development towards the practical use of high- T_c superconductors for power applications. These tapes show an improved mechanical stability and strain tolerance as compared to monofilamentary tapes.¹ For the development of Bi-2223 multifilamentary tapes in long lengths it is very important to control the defects introduced into the filaments during the deformation processes or during the formation of the superconducting phase, as defects within the filaments may alter or even impede the current flow.² Furthermore, magnetization measurements^{3–6} on tapes revealed an anomalous position of the low field or central peak, which is caused by stray fields at the grain circumferences.^{5,6} To understand the magnetic properties of such multifilamentary tapes, it is important to study in detail the flux entry, exit, and pinning within the various filaments. This task requires a *local* investigation technique, as the properties of a single filament are masked by the neighboring ones in an integral measurement. Here, we employ magneto-optic (MO) imaging,⁷ which can be carried out using an intact tape, i.e., the visualization of the flux structures is done *through* the silver sheath.^{8,9} In earlier work on Bi-2223 mono- and multifilamentary tapes using MO imaging, the flow of transport currents was visualized.^{2,10} The MO imaging technique is based on the Faraday effect in a magneto-optical active layer. Here, we have used a Bi-doped YIG film with in-plane anisotropy with a thickness of $4\text{ }\mu\text{m}$, half of which corresponds to the spatial resolution of our experiment. In order to obtain images with a relatively high contrast, an indicator film with a high field sensitivity (~ 0.1

mT) was used. The images are recorded using an 8-bit Kodak DCS 420 CCD digital camera and subsequently transferred to a computer for processing. In the MO apparatus the sample was mounted on the cold finger of an optical helium flow cryostat.¹¹ The magnetic field was applied perpendicular to the tape plane using a copper solenoid coil with a maximum field of ± 120 mT. The MO images presented here are maps of the z component of the local magnetic field, B_z .

The multifilamentary Bi-2223 tapes (19 filaments) were prepared by the “powder-in-tube” method with subsequent drawing and rolling.¹² One piece with dimensions $5 \times 3\text{ mm}^2$ cut from the tape was used for both the magnetization measurements and the MO imaging. The magnetization loops (MHLs) were recorded using a Quantum Design MPMS5 SQUID magnetometer (max. ± 5 T); with $B_{\text{ext}} \perp$ tape plane.

FIG. 1. MHLs measured on the multifilamentary tape at various temperatures 5 (outer loop), 10, 15, 20, 30, 40, and 50 K (inner loop). The anomalous position of the MHL maximum is indicated by a dashed line.

^{a)}Present address: SRL/ISTEC, 1-16-25 Shibaura, Minato-ku, Tokyo 105, Japan; electronic mail: koblishchka@istec.or.jp

FIG. 2. The peak position, B_{\max} , as a function of temperature for the multifilamentary tape (●) and a monofilamentary tape (△, from Ref. 5).

In Fig. 1, MHLs are presented in the temperature range $5 \text{ K} \leq T \leq 50 \text{ K}$. It is also clearly visible that the multifilamentary Bi-2223 tapes exhibit the anomalous position of the central peak like monofilamentary tapes. The position of the maximum, B_{\max} , is plotted in Fig. 2 and compared to data of a monofilamentary tape. At low temperatures, the maximum position increases considerably, but is always found to be less pronounced than that of the monofilamentary tape.

Figure 3 presents a MHL measured at $T=18 \text{ K}$, using the same field steps as in the following MO experiment. For comparison, a full magnetization curve is shown. The positions, where the MO images are taken, are marked using open circles. In this way, a direct comparison of MHL data and the MO flux patterns becomes possible. In all MO images presented in this paper, flux is imaged as bright, whereas well-shielded areas stay dark.

Figure 4(a) shows a polarization image of a cross section of our tape. Flux patterns obtained in increasing external field after ZFC (virgin branch, I) are presented in Fig. 4. In Fig. 4(b), flux enters the sample like in a homogeneous sample (see, e.g., Ref. 7); the edges of the outermost cores are marked by arrows. Only the outermost filaments are contributing to the current flow. When increasing the field fur-

FIG. 3. MHLs measured at $T=18 \text{ K}$. The minor loop is obtained using the same field steps as in the MO experiment. The positions of the images shown in Figs. 4 and 5 are marked by open circles.

FIG. 4. Polarization image of the tape (a) and flux patterns of the virgin branch (I); (b) 12 mT, (c) 30 mT, and (d) 45 mT. The marker in (b) is 2 mm long.

ther (c),(d), more and more filaments contribute to the current flow. The filaments in our short sample are quite uniformly penetrated by the flux. Previous observations on longer sections of multifilamentary tapes have shown that when currents encounter a defect, they may switch into a neighboring filament, and after some distance, they may return to the original one.^{2,9} This shows that the filaments in the tape are magnetically coupled together.

In Fig. 5, we show flux patterns on the return branch (II). In Fig. 5(a), a nearly homogeneous flux pattern is obtained and individual filaments cannot be resolved. On further reduction of the field (b),(c), the filaments reappear and carry pinned flux.

In the remanent state Fig. 5(d), flux remains trapped in the center of each individual filament. However, no vortices of opposite polarity can be detected in the remanent state as in the case of monofilamentary tape.⁸ In the upper part of the sample, a broad dark stripe can be seen which is the result of field overlap between two different filaments as discussed in Ref. 9. The position of the maximum in the MHL corresponds to a flux pattern like the one presented in Fig. 5(c). This does not correspond to a minimum amount of flux in the sample, which is reached only when applying a small negative field. The flux distributions within a single filament are

FIG. 5. Flux patterns of the return branch (II); (a) 45 mT, (b) 30 mT, (c) 12 mT, and (d) remanent state. The marker is 2 mm long.

found to be quite uniform. In contrast to this, most monofilamentary tapes show a “rough-looking” flux pattern at this low temperature, which is caused by a high intragranular current density; thus forcing the intergranular currents to flow around the well-shielded grains. This fact, and the large stray fields around such grains are probably responsible for

the anomalous position of the central peak in the MHL.⁵ As the grain coupling is improved along the silver sheath, this effect is not so strongly developed in the multifilamentary tapes. As a result, the peak is also shifted towards positive values, but much less pronounced as in the case of monofilamentary tapes.

In conclusion, we observed the anomalous central peak also in multifilamentary tapes, but always less pronounced than in monofilamentary tapes. Magneto-optic flux patterns reveal a quite uniform flux distribution within the filaments even at low temperatures which is a consequence of better grain growth and coupling along the silver sheath. This may be the reason for the less pronounced anomalous peak in multifilamentary tapes.

Depth-dependent magnetism of layered superconductors: Nb/Si

S. M. Yusuf,^{a)} E. E. Fullerton,^{b)} R. M. Osgood II, and G. P. Felcher

Argonne National Laboratory, Argonne, Illinois 60439

We have studied magnetic field penetration and vortex line formation in a $[\text{Nb}(100 \text{ \AA})/\text{Si}(15 \text{ \AA})] \times 20$ multilayer by magnetization and polarized neutron reflection. With the magnetic field applied parallel to the surface, the magnetization revealed the presence of a kink above H_{cl} indicative of transitions between one row of fluxoids and two rows of fluxoids parallel to the surface. The spin dependence of neutron reflectivity below H_{cl} was consistent with a penetration depth of 1200 \AA , substantially larger than that of bulk Nb. In the mixed phase ($H_{ext} > H_{cl}$) the field was found to penetrate the surface, with a slope as found in the case of $H_{ext} < H_{cl}$. At $H_{ext} > H_{cl}$ vortices form inside the multilayer, in addition to there being surface penetration. A modulation of the vortex fields was found with the periodicity of the Nb/Si bilayers as evidenced by the spin dependence of the reflectivity at the first Bragg peak of the multilayer. © 1998 American Institute of Physics. [S0021-8979(98)19411-2]

The investigation of artificially layered superconductors has drawn much attention after the discovery of anisotropic high-temperature oxide superconductors. These artificial superlattices composed of alternating superconducting/nonsuperconducting layers have been found in recent years to exhibit novel magnetic properties. These layered superconductors have a coherence length shorter than the overall film thickness. When a magnetic field H_{ext} is applied parallel to such layered structures a series of maxima occurs in the magnetization measurements at specific field strengths H_N ($H_{C1} < H_N < H_{C2}$).^{1,2} These maxima in M_z have been explained in terms of transitions between specific multichain configurations of in plane vortices.² Above H_{cl} a first row of vortices is said to be formed close to the center of the film. An increase of the field causes a compression of this one-dimensional lattice until it becomes unstable, to be replaced by two rows of fluxoids with wider spacings. This process might be repeated for any transition from n rows of fluxoids to $n + 1$. This description is fundamentally different from that given by Bean for the distribution of magnetization in a layer of type II superconductor, where the fluxoids are trapped by impurity centers.

The scope of the present work is to attempt to observe vortex configuration by polarized neutron reflection, in a system—Nb/Si multilayers—whose magnetic properties closely resembled those of Nb/Cu multilayers.^{1,2}

The $[\text{Nb}(100 \text{ \AA})/\text{Si}(15 \text{ \AA})] \times 20$ multilayer was grown by reactive dc magnetron sputtering on a silicon (15 \AA) buffer layer and protected by a silicon cap (30 \AA). The films were deposited onto 1 in. silicon wafers. From these a small piece was cut for magnetization measurements, while the remaining surface was used for neutron reflectivity. The good layering of the material was confirmed by x-ray reflectivity measurements. Magnetization measurements as a function of

temperature (at a very low fixed applied field) indicated that the $[\text{Nb}(100)/\text{Si}(15)]_{20}$ system becomes superconducting below 7.5 K (T_C). Previous transport studies have found that for 15 \AA Si layers, Nb/Si behave as a coupled three-dimensional (3D) superconductor.³

Longitudinal magnetization (M_z) measurements were carried out using a superconducting quantum interference device (SQUID) magnetometer. The field was applied parallel to the layer planes in the zero field cooled (ZFC) condition. Figure 1 shows the magnetization M_z as a function of applied field at temperatures of 5, 3, and 2 K for the $[\text{Nb}(100)/\text{Si}(15)] \times 20$ multilayer. Two distinct features are present in Fig. 1. At low applied magnetic field a flux repulsion with a constant M_z/H_{ext} value (Meissner effect) is evident. At higher fields the flux expulsion is not complete. At 2 K, the first maximum occurs at $\sim 500 \text{ Oe}$; a second maximum at $\sim 900 \text{ Oe}$. In analogy with the interpretation of the Nb/Cu data we inferred that, at the lowest temperature, 300 Oe was below H_{cl} ; at 700 Oe one row of fluxoids was close to the

FIG. 1. Magnetization (M_z) as a function of magnetic field H_{ext} applied parallel to the surface of the multilayer at 2, 3, and 5 K. The first kink is shown by a vertical arrow.

^{a)}Electronic mail: yusuf@anlps.pns.anl.gov

^{b)}Present address: IBM Almaden Research Center, San Jose, CA 95120-6099.

FIG. 2. Spin dependent reflectivities at 1.6 K and 700 Oe ZFC field. Solid dots indicate data for neutron spin parallel to the applied field (+); open circles for spins antiparallel to the field (-). In the inset: spin asymmetry $(R_+ - R_-)/(R_+ + R_-)$ in the region of the Bragg reflection.

film's center; at 1200 Oe the film contained two rows of fluxoids.

Polarized neutron reflectivity study gives information on the laterally averaged depth profile (both chemical and magnetic) as a function of the neutron momentum $Q = 2\pi \sin \theta / \lambda$, where λ is the neutron's wavelength and θ its angle of incidence with the surface.⁴ At large Q (large compared to the critical value at which the reflectivity is complete) the reflectance is the Fourier transform of the depth profile.

The instrument ("POSY I") used to record the polarized neutron reflection data is located at the Argonne Pulsed Neutron Source as described in Ref. 5. The sample temperature, in the experiments described here, was kept at 1.6 K. An electromagnet provides a vertical (perpendicular to the scattering plane) magnetic field up to 5 kOe parallel to the sample's surface. All measurements were taken in the ZFC condition.

Figure 2 depicts the R_+ and R_- as a function of Q measured at 1.6 K with $H_{\text{ext}} = 700$ Oe. Here R_+ and R_- represent, respectively, the reflectivities of neutrons with incident neutron spins parallel (+) and antiparallel (-) to the applied magnetic field on the sample. For small Q values a total reflection is observed up to the critical Q value. Beyond the critical Q value the reflectivities undergo several rapid oscillations which are due to the interference of reflections from the front and back surfaces of the multilayer. For yet larger Q values the presence of a Bragg peak is seen due to an existence of periodicity of Nb/Si layer structure with a period of 108 Å. The prominent feature of the reflectivities at and around the Bragg peak is the clear modulation of the spin asymmetry, $P = (R_+ - R_-)/(R_+ + R_-)$ (see inset of Fig. 2). This function is much more sensitive than the individual reflectivities to the magnetic depth profile. The spin asymmetry gives the most immediate signature of the magnetic character of the sample, being identically zero if the sample was nonmagnetic. The fact that nonzero P appears at the Bragg reflection indicates that the magnetic response is

FIG. 3. The spin asymmetry $P = (R_+ - R_-)/(R_+ + R_-)$ as a function of neutron momentum transfer Q at 1.6 K and with 300 Oe ZFC field. The open circles show the measured values with their error bars. The spin asymmetry calculated from the model profile discussed in the text and a penetration depth of 1200 Å is shown by a solid curve. For comparison, the spin asymmetries are calculated for 800 Å (dashed line) and 1600 Å (dotted line) penetration depths.

modulated with the Nb/Si period. No such spin dependence was seen at the Bragg peak in 300 Oe applied field.

Open circles with error bars in Fig. 3 represent the spin asymmetry of reflected neutron beam as a function of neutron wave vector transfer Q measured at 1.6 K with $H_{\text{ext}} = 300$ Oe. The region of Q spanned here is that close to total reflection: this is the region most sensitive to the penetration depth of the external magnetic field in the superconductor.⁴ To calculate the reflectivities R_+ and R_- and hence P , a model profile for the chemical structure with the following parameters was used. The thicknesses of the Si and Nb layers are 15 and 93 Å, respectively. The scattering amplitude densities are $2.07 \times 10^{-6} \text{ Å}^{-2}$ and $3.96 \times 10^{-6} \text{ Å}^{-2}$, corresponding to the bulk values for Si and Nb, respectively. The solid line shows the polarization calculated assuming that the field penetration from both the surfaces of the multilayer has the exponential form $[B(x) = H_{\text{ext}} \exp(-x/\delta)]$, where x is the distance (depth) from the surface and δ is the penetration depth. The best-fitted penetration depth δ was found to be 1200 Å (with $\chi^2 = 1$); for comparison, the spin asymmetries for penetration depth of 800 and 1600 Å are also presented. It is to be mentioned that over this Q region a similar oscillation of P was observed with 700 Oe field (not shown).

To recap the findings, for $H_{\text{ext}} < H_{\text{cl}} (=500 \text{ Oe})$ the Meissner effect has been observed with a characteristic penetration depth of 1200 Å at 1.6 K. The value of the surface penetration depth is significantly larger than that of bulk Nb [(4.2 K) = 400 Å].⁶ When H_{ext} is increased to 700 Oe ($> H_{\text{cl}}$) we have observed a modulation of the magnetic field at the interior of the film in addition to the effect of surface penetration. The vortex field which causes the interior field has the periodicity of the Nb/Si layers. This does not necessarily rule out the longer wavelength modulations predicted for these multilayers. Those, if present, would give rise to further modulations of the spin asymmetry for which longer, more accurate measurements are required. What is worth noting is the detection of sizeable magnetic fluctuations over

spacings as low as ~ 100 Å. If, in a very naive picture the fluxoids are considered to be centered at the silicon layers, and their size is given in all direction, by the penetration depth (1200 Å—found for this material), the magnetic field should be practically uniform throughout the film.

Computation of the nonlinear magnetic response of a three dimensional anisotropic superconductor

Igor Žutić^{a)} and Oriol T. Valls^{b)}

School of Physics and Astronomy and Minnesota Supercomputer Institute, University of Minnesota, Minneapolis, Minnesota 55455-0149

Many problems in computational magnetism involve computation of fields which decay within a skin depth δ , much smaller than the sample size d . We discuss here a novel perturbation method which exploits the smallness of $\epsilon \equiv \delta/d$ and the asymptotic behavior of the solution in the exterior and interior of a sample. To illustrate this procedure we consider the computation of the magnetic dipole and quadrupole moments of an anisotropic, unconventional, three dimensional superconductor. The method significantly reduces the required numerical work and can be implemented in different numerical algorithms. © 1998 American Institute of Physics.

[S0021-8979(98)19511-7]

I. INTRODUCTION

In various problems of electrodynamics, field penetration is characterized by a skin depth, δ , much smaller than the actual sample size, d . For many purposes, the approximation of zero skin depth, or that eddy currents flow only as surface sheet currents, is not sufficiently accurate, as a detailed knowledge of the field penetration or accurate values of magnetic multipoles are required. It is then important to include the small corrections arising from finite skin depth.

In this article we examine the inclusion of skin depth corrections, focusing on the magnetic response of a high temperature superconductor (HTSC). For HTSCs, it is known¹⁻³ that examining the field penetration yields important information about the unconventional electronic pairing states in these materials and the still unknown nature of high temperature superconductivity.

Although we focus on this problem, our ideas have broad validity and applications. The magnetic response of a superconductor is related to that of an ordinary conductor in an harmonically applied field. The skin effect, with $\delta \ll d$, for a quasistatic regime where the frequency is restricted by $\omega \ll c/d$ (c is the speed of light), maps⁴ onto the problem of a superconductor of the same size and shape in a static applied magnetic field. The role of δ for a conductor is taken up by λ , the effective penetration depth of a superconductor ($\lambda \ll d$). Except for the simplest geometries where an analytic solution exists for the corresponding boundary value problem, obtaining small skin depth corrections can be computationally demanding. These difficulties arise from the non-trivial boundary conditions (including open boundary equations at infinity) and the requirement that the appropriate, generally nonlinear differential equations be solved very accurately within the narrow region where the skin effects are contained. Our method offers a way to resolve these difficulties.

We examine a superconductor in an applied uniform magnetic field, \mathbf{H}_a . The sample occupies a bounded region

$\Omega \subset \mathbf{R}^3$ and at its boundary, $\partial\Omega$, is surrounded by vacuum. For H_a smaller than a critical value, a superconductor is in the Meissner regime: the magnetic flux is expelled from the bulk of the sample. On $\mathbf{R}^3 \setminus \Omega$ the current is $\mathbf{j} \equiv 0$ and it is sufficient to find a magnetic scalar potential Φ , $\mathbf{H} = -\nabla\Phi$, which satisfies the Laplace equation. On Ω , the appropriate Maxwell equation is Ampère's law. For unconventional pairing states in HTSCs, the London relation⁵ $\mathbf{j} = \mathbf{j}(\mathbf{A})$ between current and vector potential⁶ \mathbf{A} , is nonlinear and nonanalytic.^{1,2,7} Thus it is advantageous to combine Ampère's law in terms of the vector potential with the relation $\mathbf{j}(\mathbf{A})$:

$$\nabla \times \nabla \times \mathbf{A} = \frac{4\pi}{c} \mathbf{j}(\mathbf{A}). \quad (1)$$

HTSCs in general have a highly anisotropic structure with different penetration depths, λ_i , along the various, $i = a, b, c$ crystallographic directions. We include this penetration depth anisotropy through the anisotropic, nonlinear, relation $\mathbf{j}(\mathbf{A})$ given in Ref. 7. By λ we shall denote the effective penetration depth (a function of λ_i), which plays the dominant role in the field decay studied. In the special case of an isotropic superconductor with a linear relation $\mathbf{j}(\mathbf{A})$, all the fields on Ω satisfy the vector Helmholtz equation $\nabla^2 \mathbf{F} = \mathbf{F}/\lambda^2$, where \mathbf{F} can be \mathbf{H} , \mathbf{j} , \mathbf{A} . The boundary conditions are $-\nabla\Phi = \mathbf{H}_a$, at infinity, while on $\partial\Omega$ \mathbf{H} is continuous⁵ and there is no normal component of current, $j_n|_{\partial\Omega} = 0$. From the open boundary condition at infinity combined with the continuity requirement it appears that to obtain the finite skin depth corrections, one would have to solve numerically the appropriate equations in all space.

II. PERTURBATION METHOD

To resolve these difficulties, we view the finite skin effects, i.e., for finite λ in a superconductor, as a small correction to the dominant perfect diamagnetic response at $\lambda = 0$. When skin effects are studied, one has to include these corrections, which are characterized by the small parameter $\epsilon \equiv \lambda/d \ll 1$. The boundary value problem in the $\epsilon = 0$ limit is

^{a)}Electronic mail: izutic@physics.spa.umn.edu

^{b)}Electronic mail: otvalls@maroon.tc.umn.edu

relatively simple, one has only to solve the Laplace equation for the scalar potential on $\mathbf{R}^3 \setminus \Omega$ with trivial Neumann boundary conditions on $\partial\Omega$. We assume that an accurate, either analytical or numerical, solution on $\mathbf{R}^3 \setminus \Omega$ in the $\epsilon=0$ limit is available.⁷ This will be the starting point from which we shall develop our perturbation method. The small skin effect is then treated as a perturbation from the $\epsilon=0$ solution.

To proceed with the perturbation calculation we consider the auxiliary problem consisting of Eq. (1) on Ω , the $\epsilon=0$ solution on $\mathbf{R}^3 \setminus \Omega$, and the boundary conditions on $\partial\Omega$, $j_n=0$ and continuity of the tangential component of \mathbf{H} (the continuity of H_n cannot be imposed, it vanishes for the external fields in the $\epsilon=0$ limit). This is computationally simple, as it decouples the solutions for the regions $\mathbf{R}^3 \setminus \Omega$ and Ω . From this auxiliary problem we can generate⁷ the skin corrections to leading order in ϵ , as we shall now see.

In this article we consider the magnetic moment of a superconductor for an arbitrary direction of \mathbf{H}_a in a sample without a rotational symmetry (this is an extension of Ref. 7), and the magnetic quadrupole moment. We match the asymptotic behavior of the solution on $\mathbf{R}^3 \setminus \Omega$ and that in Ω by employing integral identities for magnetic multipoles.⁷ At large distances from Ω , the multipole expansion of the fields can be considered and the asymptotic behavior is governed primarily by the lowest nonvanishing multipole term. There are two different ways to obtain the multipole moments: by examining the asymptotic behavior on $\mathbf{R}^3 \setminus \Omega$, and from the fields computed on Ω . By matching the asymptotic behavior we mean that the exact solution on $\mathbf{R}^3 \setminus \Omega$ is formally written in terms of the unknown multipole moments which must agree with those computed from the fields on Ω . We formulate integral identities to compute the magnetic multipoles from fields on Ω such that we can identify terms in these expressions which are of different orders in ϵ .

The magnetic moment⁸ is

$$\mathbf{m} = \frac{1}{2c} \int_{\Omega} d\Omega \mathbf{r}'' \times \mathbf{j}(\mathbf{r}''), \quad (2)$$

where \mathbf{r}'' is the position vector for a point in Ω and \mathbf{j} is found from Eq. (1). The components of \mathbf{m} can be written for $\epsilon \ll 1$ in the form $m_i = m_{0i}[1 - \alpha_i \epsilon + O(\epsilon^2)]$, $i=x,y,z$, where m_{0i} , denoting the i th component of the magnetic moment in the limit $\epsilon=0$, represents a perfect diamagnetic response. For an ellipsoid it is given by a demagnetization factor. The α_i describe small corrections to perfect diamagnetism due to current penetration. For a direction i , where $m_{0i}=0$ (it could vanish from symmetry arguments, for a particular direction of \mathbf{H}_a), one can still have $\alpha_i \neq 0$, because of the anisotropic and nonlinear relation $\mathbf{j}(\mathbf{A})$. The effects of nonlinearity $\mathbf{j}(\mathbf{A})$, absent for $\epsilon=0$, are typically small and can be thought of as field dependent corrections to α_i , linear in H_a .

To distinguish terms in Eq. (2) of various orders in ϵ , we use Ampère's law, identities from vector calculus, and Gauss' theorem to obtain⁷

$$\begin{aligned} \mathbf{m} &= \frac{1}{8\pi} \int_{\partial\Omega} dS [\mathbf{n}(\mathbf{r}'' \cdot \mathbf{H}) + \mathbf{n} \times (\mathbf{r}'' \times \mathbf{H})] + \frac{1}{8\pi} \int_{\Omega} d\Omega \mathbf{H} \\ &\equiv \mathbf{m}_1 + \mathbf{m}_2, \end{aligned} \quad (3)$$

where \mathbf{r}'' is the position vector for a point on $\partial\Omega$ and \mathbf{n} is the unit normal pointing outwards. The terms \mathbf{m}_1 and \mathbf{m}_2 are of different order in ϵ and the latter is small, i.e., of $O(\epsilon m_0)$. This can be seen from the expression for \mathbf{m}_2 . Since \mathbf{H} is confined to a "skin" layer of thickness λ , the integral over the whole volume of Ω is effectively only an integration over the region $\sim \lambda$ away from its surface. Thus \mathbf{m}_2 vanishes in the zero penetration limit ($\epsilon=0$) and $\mathbf{m}(\epsilon=0) \equiv \mathbf{m}_0 = \mathbf{m}_1$. In order to obtain \mathbf{m} to $O(\epsilon m_0)$ it is sufficient to compute \mathbf{m}_2 to leading (zeroth) order. The term \mathbf{m}_2 explicitly scales with ϵ and any first order corrections for the fields needed to compute it would only produce contributions of order $O(\epsilon^2 m_0)$.

A similar integral identity can be derived for the magnetic quadrupole moment, defined⁹ as a symmetric traceless tensor with components

$$Q_{ij} = \frac{1}{2c} \int_{\Omega} d\Omega [(\mathbf{r}'' \times \mathbf{j}) \mathbf{r}'' + \mathbf{r}'' (\mathbf{r}'' \times \mathbf{j})]_{ij}, \quad i, j = x, y, z. \quad (4)$$

Using the previously introduced notation for terms of different order in ϵ , $Q_{ij} \equiv Q_{1ij} + Q_{2ij}$ we can derive, employing integration by parts and standard identities

$$\begin{aligned} Q_{1ij} &= \frac{1}{8\pi} \int_{\partial\Omega} dS [(n_i r_j'' + n_j r_i'')(\mathbf{r}'' \cdot \mathbf{H}) - (r_i'' H_j + r_j'' H_i) \\ &\quad \times (\mathbf{n} \cdot \mathbf{r}'')], \end{aligned} \quad (5a)$$

$$Q_{2ij} = \frac{1}{8\pi} \int_{\Omega} d\Omega [3(r_i'' H_j + r_j'' H_i) - 2\delta_{ij}(\mathbf{r}'' \cdot \mathbf{H})], \quad (5b)$$

where δ_{ij} is the Kronecker symbol. If by $Q_{0ij} \neq 0$ we denote a particular component of the magnetic quadrupole tensor in the $\epsilon=0$ limit, then, as in the case of the magnetic moment, we conclude that Q_{1ij} is of $O(Q_{0ij})$ while Q_{2ij} is of $O(\epsilon Q_{0ij})$.

Using Eqs. (4) and (5) we can match the asymptotic behavior of solutions in regions $\mathbf{R}^3 \setminus \Omega$ and Ω . It is then possible to perturbatively obtain physical quantities to leading order in ϵ , using only the fields on Ω computed from the auxiliary problem. The fields and quantities evaluated from this problem are denoted by an overbar notation. We consider first the magnetic moment. On $\mathbf{R}^3 \setminus \Omega$, the scalar potential can be written as $\Phi = \Phi_a + \Phi_r$, where Φ_a is the potential due to the applied field and satisfies the open boundary condition at infinity, $-\nabla\Phi_a \rightarrow \mathbf{H}_a$, and Φ_r describes the presence of the superconductor. Since \mathbf{m}_2 , as we have shown, explicitly scales with ϵ , it can be accurately computed to first order in ϵ by obtaining its leading contribution. This is achieved by using the fields on Ω from the auxiliary problem, i.e., by writing $\bar{\Phi} = \bar{\Phi}_a + \bar{\Phi}_r$. The task of determining \mathbf{m} to $O(\epsilon m_0)$ is therefore reduced to that of correctly including the contribution of \mathbf{m}_1 to first order in ϵ . The exact solution for \mathbf{H} is continuous on $\partial\Omega$. To calculate m_{1i} , the i th component of \mathbf{m}_1 , we can use the external fields obtained from Φ . The part of Φ , which has a dipole character is characterized by the unknown vector \mathbf{m} , the correct value of the magnetic moment. The remaining part of Φ , has different

symmetry properties and does not contribute⁷ to m_i . Contributions to the i th component of \mathbf{m}_1 , $i=x,y,z$, (we take $m_{0i} \neq 0$) can be written as

$$m_{1i}(\mathbf{m}) = m_{1i}(\Phi_a) + m_{1i}(\Phi_r), \quad (6)$$

where $m_{1i}(\Phi_a)$, for Φ_a , which is known, can be simply calculated from Eq. (4). We define p_{ij} by $m_{1i}(\Phi_a) \equiv \sum_j p_{ij} m_{0j}$, $i, j=x,y,z$. The constants p_{ij} , which depend on the shape of Ω , can now be determined by solving for p_{ij} using the known values $m_{1i}(\Phi_a)$ and m_{0i} corresponding to \mathbf{H}_a applied along three independent directions. In the limit $\epsilon=0$, $m_{2i}=0$ and from Eq. (6) follows the identity

$$m_{0i} = \bar{m}_{1i} = \sum_j p_{ij} m_{0j} + \sum_j (\delta_{ij} - p_{ij}) m_{0j}, \quad (7)$$

where $m_{1i}(\Phi_r) = \sum_j (\delta_{ij} - p_{ij}) m_{0j}$. For $\epsilon \neq 0$, when the solution for Φ and \mathbf{H} is given in terms of a multipole expansion with unknown coefficients, $m_{1i}(\Phi_a)$ remains the same. The terms in Φ_r which contribute to the magnetic moment \mathbf{m} , will now have coefficients proportional to the correct unknown value of \mathbf{m} , slightly changed from the $\epsilon=0$ case. We can therefore write $m_{1i}(\Phi_r) = \sum_j (\delta_{ij} - p_{ij}) m_j$ and the correct value for m_{1i} satisfies $m_{1i} = \sum_j [m_{ij} - p_{ij}(m_{ij} - m_{0ij})]$. Employing the fact that m_{2i} and \bar{m}_{2i} agree to $O(\epsilon m_{0i})$ we can solve for m_i from $m_i = \sum_j [\delta_{ij} m_{ij} - p_{ij}(m_{ij} - m_{0ij})] + m_{2i}$, with the solution for m_i correct to $O(\epsilon)$:

$$m_i = m_{0i} + \sum_j p_{ij}^{-1} m_{2j} \approx m_{0i} + \sum_j p_{ij}^{-1} \bar{m}_{2j}. \quad (8)$$

Therefore the magnetic moment can be computed by only determining the lowest order contribution to m_2 .

Following an analogous procedure we can obtain a solution for the components of the quadrupole tensor Q_{ij} accurate to first order in ϵ . The resulting expression is similar to Eq. (8) with the constants p_{ij} replaced by the appropriate fourth rank tensor.

As a simpler example, it is instructive to consider an isotropic, linear superconducting sphere in an applied uni-

form magnetic field. Eq. (8) reduces¹⁰ to the analytical result⁵ $m = m_0(1 - 3\epsilon)$, where $m_0 = -H_a a^3/2$, $\epsilon \equiv \lambda/a$ and a is the sphere radius.

III. CONCLUSIONS

The ideas presented here can be used in problems in computational magnetics involving a small skin depth, by incorporating our perturbation procedure in the appropriate numerical algorithm. The integral identities for the magnetic multipoles are valid in the quasistatic regime and not restricted to the field of superconductivity.

We have addressed here the computation of small skin effects in a superconductor, using the perturbation method and matching the asymptotic behavior of a solution. We have shown how to accurately compute the nonlinear magnetic response of an anisotropic superconductor, by simplifying the boundary conditions and reducing the size of the computational domain.

Temperature dependence of giant magnetoresistance properties of NiMn pinned spin valves

Sining Mao,^{a)} Nurul Amin, and Ed Murdock

Seagate Technology, 7801 Computer Avenue, Minneapolis, Minnesota 55435

The giant magnetoresistance response of NiMn pinned spin valves was studied at elevated temperature. Top spin valve films were made by ion beam sputtering and thermally treated to induce the strong unidirectional pinning field in the pinned layer. Both δR and $\delta R/R$ decrease linearly with temperature. The sheet resistance of the spin valves also increases linearly with temperature. The exchange coupling between pinned layer and free layer decreases slightly and the coercivity of the free layer increases slightly. The temperature dependence of the exchange pinning field is unique in NiMn spin valves. The pinning field has a weakly increasing temperature dependence up to 200 °C, then decreases to zero at the blocking temperature of 380 °C. Samples with different thickness NiMn layers show different temperature dependencies. However, the blocking temperature is unchanged. The pinning fields of NiMn, FeMn, IrMn, and NiO spin valves were also measured up to 200 °C; NiMn pinned spin valves show the least dependence of pinning field at elevated temperatures. © 1998 American Institute of Physics. [S0021-8979(98)27811-X]

INTRODUCTION

In spin valve recording heads, a sufficient pinning field [due to exchange coupling between an antiferromagnetic (AFM) pinning layer and a ferromagnetic (FM) pinned layer] is required to keep the pinned layer's magnetization unchanged during the operation of the spin valve (SV)/giant magnetoresistance (GMR) reader. So far various AFM materials, such as FeMn, NiO, NiMn, IrMn, PdPtMn, and TbCo, have been exploited as pinning layers in SV/GMR transducers.¹ NiMn has the strongest pinning strength (H_p) at high temperatures,^{2,3} while most AFM materials can be made with high H_p at room temperature but insufficient H_p for use of spin valve heads at elevated temperatures. In practice, MR-type recording heads operate at rather high internal temperatures. The stripe temperature can be as high as 200 °C. Moreover, thermal asperity events may temporarily create a much higher stripe temperature. The pinning must remain high at these temperatures.

In the as-grown phase the NiMn has a face-centered-cubic (fcc) structure which is not antiferromagnetic. A thermal treatment is needed to induce the fcc to face-centered-tetragonal (fct) phase transformation in the NiMn layer to provide the exchange field to the ferromagnetic layer through antiferromagnetic-ferromagnetic interaction. Such thermal annealing tends to damage the GMR properties of a spin valve. Careful film deposition and postannealing are needed to produce thermally stable NiMn spin valves (i.e., able to survive the aggressive NiMn annealing).² In this article, we present the temperature dependence of the pinning field and magnetoresistance of NiMn spin valves made by ion beam

deposition. In addition, a comparison between different pinning materials is also given.

EXPERIMENT

Spin valve films were deposited by a commercial multi-target ion beam sputtering apparatus, which has a base pressure of 1×10^{-8} Torr. A spin valve stack of a 80 Å Ta/ t Å NiMn/25 Å NiFe/15 Å Co/30 Å Cu/15 Å Co/55 Å NiFe/25 Å Ta substrate was sequentially deposited at deposition rates of 0.5–1 Å/s without breaking vacuum. Bilayers of the Ta/NiMn/NiFe/Ta substrate were made under the same conditions for a pinning field comparison. After deposition of the spin valves, a high temperature thermal anneal (~ 280 °C) in a static magnetic field for as long as 45 h was performed to further treat the films and to induce exchange coupling between NiMn and NiFe. The range of thickness t for the NiMn pinning layer is 80–500 Å. The pinned layer NiFe thickness was varied from 25 to 250 Å to study the pinning field variation. It shows a typical $1/t$ relationship with respect to the ferromagnetic layer thickness.³ The spin valves were characterized for structural properties using x-ray diffraction (XRD) (including a rocking curve scan). The films are highly (111) textured. High resolution cross-sectional transmission electron microscopy (TEM) images indicate the high quality of the interface microstructures.⁴ The magnetoresistance was measured by a dc four point probe method at different temperatures on a commercial GMR tester in air. Because of the use of the Ta cap layer no surface oxidation was observed during the measurement. A vibrating sample magnetometer (VSM) with a high temperature attachment was used for magnetization measurements on selected samples. Films with the same spin valve stack as NiMn were deposited us-

^{a)}Electronic mail: sining_mao@notes.seagate.com

FIG. 1. Temperature dependence of the GMR ($\Delta R/R$) and ΔR for a NiMn spin valve.

ing IrMn, FeMn, and NiO pinning materials and measured between room temperature (RT) and 200 °C for comparison.

RESULTS AND DISCUSSION

Results of the GMR and ΔR from the high temperature GMR measurements of a spin valve are shown in Fig. 1. This is representative of all the NiMn spin valves with different thickness combinations. The GMR is defined by the resistance difference between the parallel state and the antiparallel state divided by the parallel state resistance. The R - H curves are similar to each other at different temperatures. The pinned layer has a very strong pinning field (typically >500 Oe) and is not switched up to 800 Oe.² The GMR response is inversely proportional to temperature between RT and 200 °C. The temperature coefficients of the GMR ratio and ΔR are $-0.36\%/^{\circ}\text{C}$ and $-0.23\%/^{\circ}\text{C}$, respectively. Low temperature GMR measurements confirmed the linear ΔR variation over a broader temperature range.⁵ This is consistent with our previous observation on FeMn spin valves but different from the bulklike T^n power law temperature dependence (where $n=1.5$), indicating a contribution from an intrachannel spin-mixing process in addition to the interchannel spin-mixing process.⁶

The reversible resistance increase of NiMn spin valves follows a simple linear relationship with temperature due to electron-phonon scattering. The increase of the normalized sheet resistance is plotted in Fig. 2 and is also compared with a MR film. The spin valve films have less increase in resis-

FIG. 2. Temperature dependence of the normalized resistance for a NiMn spin valve and a 225 Å NiFe MR film.

FIG. 3. Coercivity of the free layer and the exchange coupling field between the free layer and the pinned layer as a function of temperature.

tance than the AMR films. This will reduce the sensor self-heating effect and improve resistance to thermal spikes. The free layer magnetic properties are shown in Fig. 3. The coercivity of the free layer of Co/NiFe increases a little bit and the exchange field between the free layer and the pinned layer due to orange peel coupling decreases by 15% at 200 °C. The origin of the increase of free layer coercivity is unclear at this moment although it may be related to the magnetic interaction with the pinned layer.

Figure 4 is the pinning field dependence on the temperature in the range of RT~200 °C for NiMn, FeMn, IrMn, and NiO spin valves made at Seagate. Since the absolute value of the pinning field depends on the thickness of all the layers and their process details, only the normalized data are plotted to illustrate the temperature dependence. Figure 4 shows the dramatic difference between NiMn and the rest; NiMn spin valves retain their full pinning strength to nearly 200 °C. This is very important for practical recording heads whose active sensor operating environment is very hot. The blocking temperatures for FeMn, NiO, and IrMn are 150, 200, 220 °C, respectively. They are consistent with the published data.^{1,7} However, the blocking temperature of NiMn spin valves (380 °C, see Fig. 5) is much higher than that of all the other pinning materials. Furthermore the NiMn pinning field does not follow a $(1-1/T)$ relationship with temperature which is common among IrMn, FeMn, and NiO materials.⁷ The typical linear temperature dependence was shown by

FIG. 4. Normalized pinning fields vs temperature for NiMn, FeMn, IrMn, and NiO spin valves.

FIG. 5. Temperature dependence of the pinning field for NiFe/NiMn bilayers. The NiFe layer thickness is 250 Å and the NiMn layer thicknesses are 125, 250, and 500 Å, respectively. The grain sizes of the NiMn layers are 80, 190, and 260 Å, respectively.

Malozemoff based on thermal excitation⁸ and experimentally observed in various materials systems.^{9–11} The linear temperature dependence is also accompanied by a broader local blocking temperature distribution.^{7,11}

To further understand the unique temperature dependence of the pinning fields, we investigated the temperature dependence using a high temperature VSM on the NiMn/NiFe bilayers over a 500 °C range. The data are plotted in Fig. 5. It is very interesting to see that the temperature dependence of the NiMn depends upon the NiMn layer thickness and deviates from an inversely linear dependence. More important, the blocking temperature is the same for different layers thicknesses which again is quite different from other materials [like IrMn (Ref. 12) and NiO (Ref. 13)]. As pointed out by Lin *et al.*,⁷ the NiMn exchange coupling is through interaction of NiFe and NiMn antiferromagnetic clusters. The blocking temperature is primarily determined by the NiFe layer's ferromagnetic properties since the Néel temperature for NiMn is far above the blocking temperature, unlike the other materials which have much lower Néel temperatures.

The intrinsic antiferromagnetic crystalline anisotropy of the NiMn layer and the interfacial coupling strength are two dominant factors determining the pinning field.⁷ The temperature dependence of the pinning strength in NiMn films thicker than the critical thickness is mostly dominated by the uncompensated spin structures at the interface and the temperature dependence is similar to NiFe/CoO superlattice results.¹⁴ The microstructure of the NiMn will definitely influence the pinning strength and, further, the temperature dependence of the pinning field. To verify the hypothesis, we performed XRD and derived the grain size for the three samples, noted in the caption for Fig. 5. The smaller grains

in the thinner NiMn are more susceptible to thermal fluctuations and lose their AFM ordering easily, while the larger grain size helps to stabilize the AFM order against thermal energy and contributes to an insensitive temperature dependence. This implies that the blocking temperature distribution of the NiMn spin valves is also narrower. A complete study of the blocking temperature distribution is currently underway.

SUMMARY AND CONCLUSIONS

In summary, we have reported the magnetic and electrical responses of NiMn spin valves at elevated temperatures. The NiMn spin valves have a linear temperature response in terms of resistance, $\delta R/R$, δR , exchange field, and coercivity of the free layer. The temperature coefficient of resistance of NiMn spin valves is much smaller than conventional MR films. The pinning field is only weakly dependent on temperature (<200 °C) when the thickness of the NiMn pinning layer is sufficient (~250 Å). NiMn spin valves have the strongest pinning field at 200 °C of any AFM material published to date, and are very promising for spin valve head applications.

The interfacial coupling energy, $\Delta\sigma$ for polycrystalline $\text{Ni}_{0.8}\text{Fe}_{0.2}$ (100 Å)/ $\text{Mn}_x\text{Pt}_{1-x}$ (t Å)/ SiO_2 bilayers, has been determined from wedge samples spanning a $\text{Mn}_x\text{Pt}_{1-x}$ composition range $0.42 < x < 0.76$ and $t \sim 350$ Å. $\Delta\sigma$ exhibits a sharp peak of 0.1 erg/cm^2 at 51% Mn. We compare the magnetic and microstructural properties of two bilayer films, which have the same compositions of permalloy and $\text{Mn}_x\text{Pt}_{1-x}$: [$\text{Ni}_{0.85}\text{Fe}_{0.15}$ (100 Å)/ $\text{Mn}_{0.49}\text{Pt}_{0.51}$ (t Å)]. In one case (normal structure), the epitaxial permalloy was grown first onto Pt/MgO(001), followed by 170 Å of $\text{Mn}_{0.49}\text{Pt}_{0.51}$. In the other structure (inverted), a 350 Å thick polycrystalline film of $\text{Mn}_{0.49}\text{Pt}_{0.51}$ was grown onto a SiO_2 substrate, followed by permalloy. The structures exhibited very different exchange bias fields (32 versus 86 Oe) and $\Delta\sigma$ values (0.021 versus 0.060 erg/cm^2), respectively. Significant differences in texture, grain size, and $\text{Mn}_{0.49}\text{Pt}_{0.51}$ layer thickness for the two samples are reported. © 1998 American Institute of Physics. [S0021-8979(98)47611-4]

The key to the performance¹ of spin valve structures is the pinning of a ferromagnetic layer, such as permalloy, by exchange biasing using an antiferromagnetic (AFM) layer.² Various AFM materials are being explored to achieve the desired pinning characteristics, temperature stability, and minimal postprocessing. These include NiMn and ternary $\text{Mn}_{1-x-y}\text{Pt}_x\text{Pd}_y$ alloys.^{3,4} $\text{Mn}_x\text{Pt}_{1-x}$ films not only show good promise as an exchange bias material but their high Néel temperature results in a high blocking temperature when they are exchange coupled with permalloy.⁵ In this paper we report on the exchange biasing in permalloy- $\text{Mn}_x\text{Pt}_{1-x}$ bilayer films, as a function of composition. Detailed electron microscopy investigation to elucidate the role of microstructure and composition in determining the strength of the interfacial coupling is also presented.

The films were grown by coevaporation in a molecular beam epitaxy system under ultrahigh vacuum ($\sim 10^{-10}$ mB). To determine the dependence of $\Delta\sigma$ on $\text{Mn}_x\text{Pt}_{1-x}$ layer composition, wedge samples were prepared, of the inverted type, comprised of $\text{Ni}_{0.85}\text{Fe}_{0.15}$ (100 Å)/ $\text{Mn}_x\text{Pt}_{1-x}$ (t Å)/ SiO_2 in which the composition x was graded spatially, covering the range $x = 0.42$ – 0.54 . The Py layer thickness and composition were constant across the wedge while the $\text{Mn}_x\text{Pt}_{1-x}$ thickness varied from 300 to 400 Å. This thickness variation was shown in separate experiments not to influence $\Delta\sigma$ significantly. The samples were grown in a dc magnetic field (~ 1 kOe, in the film plane, as for all the samples described in this article) and the substrate was held at 40 – 50°C . After growth, the samples were annealed (in the field) for 2 h at 180°C to achieve chemical ordering of the $\text{Mn}_x\text{Pt}_{1-x}$.

Two other samples (unwedged) were studied in this work. For these, the composition and thickness of the Py layer as well as the composition of the $\text{Mn}_x\text{Pt}_{1-x}$ layer were

kept constant and the same for both samples. The structures were: 10 Å Pt/170 Å $\text{Mn}_{0.49}\text{Pt}_{0.51}$ /100 Å $\text{Ni}_{0.85}\text{Fe}_{0.15}$ /10 Å Pt/MgO(001); referred to as SV1098 and 100 Å $\text{Ni}_{0.85}\text{Fe}_{0.15}$ /350 Å $\text{Mn}_{0.49}\text{Pt}_{0.51}$ / SiO_2 ; referred to as SV1171. The Pt seed layer was grown at 700°C and shown by *in situ* (reflection high-energy electron diffraction) (RHEED) analysis to be epitaxial, i.e., Pt(001)/MgO(001). The sample temperature was then reduced to 200°C for growth of Py and $\text{Mn}_{0.49}\text{Pt}_{0.51}$ films in a dc magnetic field. RHEED showed that the Py was epitaxial, i.e., Py(001)/Pt(001), but the $\text{Mn}_{0.49}\text{Pt}_{0.51}$ exhibited diffuse arcs indicating multiple orientations of this layer. In the case of SV1171, the entire structure was grown at $\sim 30^\circ\text{C}$ in a dc magnetic field and subjected to a subsequent anneal at $180^\circ\text{C}/2 \text{ h}$.

Following growth, samples SV1098 and SV1171 were characterized structurally, and their bulk compositions were determined by a combination of Rutherford backscattering spectroscopy and proton induced x-ray emission spectroscopy. In addition, local compositions were measured by x-ray emission spectroscopy in a transmission electron microscope (TEM) using a 100 Å probe and experimentally measured k factors.⁶ Energy-filtered images of the characteristic edges in electron energy-loss spectroscopy were obtained using a TEM equipped with a field-emission source and a commercial image filter. The interfaces were characterized by high-resolution electron microscopy.

Figure 1 shows the dependence of $\Delta\sigma$ on the composition (x) of $\text{Mn}_x\text{Pt}_{1-x}$ determined from point-by-point measurements, at room temperature, of the longitudinal Kerr loops of the wedge structure. $\Delta\sigma$ was determined from the exchange bias using the expression: $\Delta\sigma = H_e M_s t$ following Malozemoff.⁸ Here, H_e is the exchange bias field, and M_s and t are the saturation magnetization and thickness of the Py film, respectively. Data for individual inverted structures of compositions outside the wedge range are also included in Fig. 1. We note that for bulk $\text{Mn}_x\text{Pt}_{1-x}$ crystals the Néel

^{a)}Electronic mail: krishnan@lbl.gov

temperature (T_N) peaks near $x=0.50$.⁷ Similar composition dependence of T_N and $\Delta\sigma$ suggests a common origin, namely, as the crystal composition departs from the chemical-ordering composition ($x=0.5$), Mn either occupies sites outside the (001) sheets of antiferromagnetically aligned Mn (for $x>0.5$) or Pt occupies sites within the sheets (for $x<0.5$). In both cases, more Mn moments become uncompensated leading to diminished antiferromagnetic ordering. Kishi *et al.*³ report a similarly sharp peak near $x=0.5$ in H_e for exchange-coupled Py/MnPtPd structures.

The inset to Fig. 1 shows the longitudinal Kerr loops, recorded along the easy axis, for these samples. Both samples show a unidirectional shift in their hysteresis loops with exchange bias values of 32 Oe (SV1098) and 86 Oe (SV1171). The $\Delta\sigma$ values, calculated from these fields, are shown in Fig. 1. The value of $\Delta\sigma$ (0.060 erg/cm^2) for SV1171 is in good agreement with the wedge data for a sample of similar structure and composition. On the other hand, sample SV1098 has a much reduced value of $\Delta\sigma$ (0.022 erg/cm^2).

Specular ($\theta-2\theta$) x-ray diffraction scans for SV1098 confirmed a single orientation of Py: Py (001)/Pt,MgO(001). They also revealed multiple orientations of the $\text{Mn}_{0.49}\text{Pt}_{0.51}$ film, each having the chemically ordered tetragonal structure ($a=4.004 \text{ \AA}$, $c=3.664 \text{ \AA}$). The dominant orientation was $\text{Mn}_{0.49}\text{Pt}_{0.51}$ (100)/Py(001). For SV1171, the specular scan showed only a (111) peak for Py indicating a dominant (111) texture. All remaining peaks could be indexed on the basis of the chemically ordered, tetragonal phase of $\text{Mn}_{0.49}\text{Pt}_{0.51}$. Multiple peaks were present, indicating polycrystallinity with no preferred texture axis.

To understand the role of microstructure and composition, the two samples (SV1098, SV1171), were studied by electron microscopy. For sample SV1098, Fig. 2 shows a bright-field (BF) image (a), the corresponding selected area diffraction (SAD) pattern (b) and a dark-field image (c) using a portion of the Ni-Fe(112) ring (d). These images, taken from a thin ($t\sim 1000 \text{ \AA}$) area of the sample show that the grains with sizes $\sim 5 \text{ nm}$ have a significant in-plane rotation. The SAD pattern can be indexed to a combination of face-centered-cubic Ni-Fe ($a\sim 3.54 \text{ \AA}$), and Mn-Pt with an elementary tetragonal cell ($a\sim 2.82 \text{ \AA}$, $c\sim 3.69 \text{ \AA}$). The in-plane rotation of the grains is evident from the angular spread of both sets of spots in Figs. 2(b) and 2(d). Even though earlier $\theta-2\theta$ x-ray diffraction scans have confirmed good epitaxy, it appears that large-angle grain boundaries and significant mismatch in plane ($\sim 30^\circ$) between the grains abound. No evidence for the chemical ordering of $\text{Mn}_{0.49}\text{Pt}_{0.51}$ is readily discernible from these complicated SAD patterns. However, clear evidence for the ordering is seen in a microdiffraction pattern superstructure reflections [Fig. 2(e)], taken from a single grain using an 8 nm focused electron probe. A number of grains showed this feature but it is clear from this limited sampling that not all grains are chemically ordered. Similar analysis of sample SV1171 is shown in Figs. 2(f) (BF image) and 2(g) (SAD). Figure 2(f) shows a similar grain-size distribution to Fig. 2(a). The rings in the SAD pattern can be indexed to polycrystalline SiO_2 and $\text{Mn}_{0.49}\text{Pt}_{0.51}$ (grain size $\sim 5 \text{ nm}$). No evidence for NiFe is

FIG. 1. Interfacial coupling energy density $\Delta\sigma$ as a function of composition for $\text{Ni}_{0.85}\text{Fe}_{0.15}$ (100 Å)/ $\text{Mn}_x\text{Pt}_{1-x}$ (300–400 Å)/ SiO_2 . The solid points are from a wedge sample, and open circles are from individual samples (error bars within data circles). The inset shows two representative longitudinal Kerr loops for samples SV1098 and SV1171, which have the same composition of $\text{Mn}_x\text{Pt}_{1-x}$ ($x=0.49$). The ordinate is the Kerr rotation on a normalized scale. The corresponding values of $\Delta\sigma$ for these samples are plotted as a filled (SV1098) and open (SV1171) triangles.

seen in the SAD pattern. There is only one weak shoulder on the side of the $\text{Mn}_{0.49}\text{Pt}_{0.51}$ (200) peak that shows up for Py in the electron diffraction pattern; perhaps this line was undetected or the thin layer was removed in the ion-milling process. Local compositions of the films were both $\text{Mn}_{0.49}\text{Pt}_{0.51}$ but the permalloy compositions were $\text{Ni}_{0.87}\text{Fe}_{0.13}$ and $\text{Ni}_{0.85}\text{Fe}_{0.15}$ for SV1098 and SV1171, respectively.

The nature of the interface and the chemical integrity of the various layers were studied by both energy-filtered imaging and high-resolution phase contrast imaging of cross-section samples. Using this technique, features in the characteristic energy-loss edges of the constituent elements can be measured both at high-energy ($\sim 1 \text{ eV}$) and spatial ($\sim 1-2 \text{ nm}$) resolution. Typically, in the electron microscope dipole selection rules, $\Delta l = \pm 1$ apply and the core edges of interest are the $1s \rightarrow p(K)$, $2p \rightarrow d(L)$, and $3d \rightarrow f(M)$ transitions. Specifically, for the elements of interest this would correspond to the K edges for oxygen (532 eV) and magnesium (1305 eV), L edges for manganese ($L_3 \sim 640 \text{ eV}$, $L_2 \sim 651 \text{ eV}$), iron ($L_3 \sim 708 \text{ eV}$, $L_2 \sim 721 \text{ eV}$), and nickel ($L_3 \sim 855 \text{ eV}$, $L_2 \sim 872 \text{ eV}$), and the $O_{2,3}$ edge for platinum (52 eV). Energy-filtered maps (using 10 eV windows) for cross-section samples of SV1098, after background subtraction and suitable correction to accommodate any thickness variations, along with a low-magnification image (a) and a high-resolution image of the interface (b) are shown in Fig. 3. The individual layers corresponding to MgO, NiFe, and Mn-Pt are clearly evident from the overlap of the images from their respective constituent elements. Within the resolution of this measurement the interfaces between the three layers are chemically sharp and are devoid of any pinholes. A similar result was also obtained for sample SV1171, but in the interest of brevity these energy-filtered images are not included in this article. Finally, the high-

FIG. 2. Plan-view images and selected area diffraction for the two samples. Notice the reflection corresponding to chemical ordering in (e).

resolution electron microscope image reveals that the interface between the permalloy and Mn–Pt is structurally quite rough with significant strain.

The key result is that our data show a much reduced interfacial coupling for the epitaxial Py/Mn_{0.49}Pt_{0.51} sample (SV1098) in comparison with the inverted polycrystalline Py/Mn_{0.49}Pt_{0.51} sample (SV1171). Apart from the different crystallographic texture of the two structures, other differences include a small but significant difference in grain size and a large thickness difference of Mn_{0.49}Pt_{0.51}. Note that the model of Malozemoff⁸ does predict a linear dependence of $\Delta\sigma$ on the reciprocal of the domain size of the antiferromagnet. The smaller crystallographic grain size of SV1171 compared with SV1098 leads one to expect a smaller domain size, though this remains to be confirmed experimentally. Another difference between the samples may be that the degree of chemical ordering for sample SV1098 is less than for SV1171, leading to incomplete antiferromagnetic ordering in

FIG. 3. Cross-sectional images and energy-filtered elemental images for sample SV1098.

this sample. The microdiffraction data for SV1098 do indicate incomplete and inhomogeneous ordering while the x-ray data for SV1171 are consistent with complete chemical ordering. A further structural difference between the samples is that in SV1098 the orientation of the interface plane of the antiferromagnet is predominantly (100), which is a plane of uncompensated Mn moments. Koon⁹ has predicted a smaller $\Delta\sigma$ value for such a plane compared with a compensated plane. However, we believe that the most likely explanation for the large difference in $\Delta\sigma$ in the present samples is that the thickness (170 Å) of Mn_{0.49}Pt_{0.51} in SV1098 may be approaching a critical thickness for exchange biasing.

We report unusually large room temperature coercive field H_c induced in $\text{Ni}_{0.81}\text{Fe}_{0.19}$ films grown on the (001) magnetically compensated surface of antiferromagnetic single crystal CsCl-type $\text{FeRh}_{0.95}\text{Ir}_{0.05}$ alloy thin layers on MgO (001) substrates. The specimens were prepared by conventional rf sputtering in Kr atmosphere, at 450–500 °C for FeRh–Ir and 20–200 °C for NiFe. The epitaxial growth of NiFe/FeRh–Ir and atomically flat terraces of FeRh–Ir were confirmed by x-ray reflectometry and scanning tunneling microscopy. For a NiFe(2.7 nm)/FeRh–Ir(22 nm) film, a maximum H_c of 810 Oe is observed. The $1/t_{\text{NiFe}}$ dependence of H_c for larger NiFe thicknesses indicates that the large coercive field originates from the magnetic interaction at NiFe/FeRh–Ir interface. The large H_c combined with high corrosion resistance make FeRh based alloys a promising candidate for application as pinning layers in spin-valve devices. © 1998 American Institute of Physics. [S0021-8979(98)29011-6]

I. INTRODUCTION

Thin antiferromagnetic films are currently attracting considerable attention of many researchers because they serve as pinning layers in spin valve structures. For the applications in spin valve based devices, it is essential to use the antiferromagnets with a high pinning force and a strong corrosion resistance. This is why we focused our interest on FeRh-based alloys.

FeRh alloys between 48 and 52 at. % of rhodium display an ordered CsCl (or B2) structure and are antiferromagnetic (AF) at room temperature. Under heating they exhibit a first order transition at a temperature $T_0 \sim 340$ K to a ferromagnetic (FM) state, as observed by Fallot and Hocart.¹ Extensive experimental and theoretical studies of structural and magnetic properties of these unusual materials were performed by several researchers. The AF–FM transformation is accompanied by a lattice expansion of about 0.3% while preserving the CsCl structure.²

Neutron diffraction experiments³ showed that iron atoms have an enhanced magnetic moment in the both AF and FM states [$\mu_{\text{Fe}}(\text{AF}) \sim 3.3 \mu_B$, $\mu_{\text{Fe}}(\text{FM}) \sim 3.1 \mu_B$]. Rhodium atoms have no appreciable moment in AF state while $\mu_{\text{Rh}}(\text{FM}) \sim 1.0 \mu_B$. These results are in a very good agreement with the conclusions of band structure calculations.^{4,5} In contrary to Mn-based antiferromagnets, the AF coupling in FeRh alloys takes place between successive ferromagnetically ordered (111) planes of Fe atoms.⁴

Preparation of the ordered FeRh alloy thin films is quite difficult since the structure and magnetic properties are very sensitive to the stoichiometry. We note that the CsCl ordering occurs for Rh content from 20 to 52 at. %, but the AF state is established only between 48 and 52 at. % of Rh.⁶

Lommel⁷ fabricated thin films of ordered FeRh alloy by several methods (alternate Fe and Rh deposition followed by diffusion anneal, codeposition and sputtering at 300 °C). More recently, other authors have tried cosputtering from Fe and Rh targets onto glass, followed by anneal at 600–1200 °C^{8,9} or by coevaporation.¹⁰ The common property of these films was a presence of paramagnetic disordered fcc phase, which appears probably due to an increased local concentration of Rh (on atomic scale) during the deposition and which reduces the growth of CsCl ordered structure.⁸ The retained fcc phase strongly affects the AF–FM transition, which is well manifested when measuring the magnetization as a function of temperature during heating cycles.^{7,8}

For practical applications as antiferromagnetic layers in spin valves operating at “usual” temperatures it is necessary to raise the transition temperature T_0 up to 450–500 K. This can be obtained by replacing about 5% of rhodium atoms with iridium.¹¹

As recently reported,¹² we can successfully grow $\text{FeRh}_{0.95}\text{Ir}_{0.05}$ ordered alloy (001) epitaxial films by sputtering from an alloy target on MgO (001) substrates heated above 300 °C. In this article, we present structural and magnetic properties of exchange coupled $\text{Ni}_{0.81}\text{Fe}_{0.19}/\text{FeRh}_{0.95}\text{Ir}_{0.05}$ epitaxial films on MgO (001) substrates.

II. SAMPLE PREPARATION AND CHARACTERIZATION

$\text{FeRh}_{0.95}\text{Ir}_{0.05}$ films were prepared by a conventional rf sputtering from alloy target (60 mm in diameter) on cleaved (001) surfaces of MgO substrates, heated up to 450–500 °C, under Kr pressure, $p(\text{Kr})$, of 8×10^{-3} Torr, at a rate of 0.05 nm/s. The film thickness ranged from 6 to 200 nm. After deposition, the films were annealed at the deposition temperature for 30–60 min.

A permalloy layer $\text{Ni}_{0.81}\text{Fe}_{0.19}$ was grown afterwards on each $\text{FeRh}_{0.95}\text{Ir}_{0.05}$ film, which was either water cooled or

FIG. 1. X-ray diffraction θ - 2θ scans of $\text{NiFe}(t_{\text{NiFe}})/\text{FeRh-Ir}(22 \text{ nm})/\text{MgO}(001)$ samples for $25^\circ \leq 2\theta \leq 100^\circ$. The whole scans are shown for FeRh-Ir buffer without NiFe layer and for $t_{\text{NiFe}}=3 \text{ nm}$. For $t_{\text{NiFe}}=2$ and 4.5 nm , the most important parts of the scan with NiFe(022) diffraction peak are also included.

kept at temperatures up to 200°C . Permalloy was sputtered from an alloy target under $p(\text{Kr}) \sim 8 \times 10^{-3}$ Torr, at a rate of 0.05 nm/s .

X-ray diffraction (XRD) experiments, carried out in a symmetric θ - 2θ scan using $\text{Cu } K\alpha$ radiation, confirmed that the films are epitaxial with the ordered CsCl structure (Fig. 1). No peaks of the fcc disordered phase were detected. The average interplanar spacing agrees reasonably with the lattice constant $a=0.2985 \text{ nm}$, determined in bulk $\text{FeRh}_{0.95}\text{Ir}_{0.05}$ alloys.¹³ Only small differences were observed for the films thinner than 20 nm .

Surface morphology was studied by *ex situ* scanning tunneling microscopy (STM) using Nanoscope III equipment (Digital Instruments, Inc.) with a tungsten tip. These observations revealed that the FeRh-Ir surface consists of atomically flat (001) terraces of 100 nm average lateral size (Fig. 2). The terraces are separated by steps with a minimum height of approximately 0.3 nm , corresponding to the lattice parameter a of the CsCl structure, which indicates a layer-

FIG. 2. Typical STM image of $324 \times 324 \text{ nm}^2$ surface of 200-nm -thick FeRh-Ir ordered alloy film on $\text{MgO}(001)$ substrate. The edges of the picture are parallel with $\text{MgO}[100]$ and $\text{MgO}[010]$ directions.

FIG. 3. Coercive field H_c in $\text{NiFe}(t_{\text{NiFe}})/\text{FeRh-Ir}(22 \text{ nm})/\text{MgO}(001)$ structure as a function of t_{NiFe} . The most interesting region, where H_c reaches its maximum, is magnified in the left inset. To justify the $1/t_{\text{NiFe}}$ behavior of H_c for thicker NiFe layers, we plotted H_c against $1/t_{\text{NiFe}}$ in the right inset.

by-layer growth process. The expected crystallographic relation between the alloy film and the MgO substrate is: $\text{FeRh-Ir}(001) \parallel \text{MgO}(001)$ and $\text{FeRh-Ir}[100] \parallel \text{MgO}[110]$, which means, that FeRh-Ir(001) layer grows epitaxially on MgO(001) with the unit cell rotated by 45° in the plane of the sample. Thus, the STM observations reveal, that the steps separating the FeRh-Ir terraces are parallel with FeRh-Ir $[100]$ and $[010]$ directions (Fig. 2).

XRD measurements showed that $\text{NiFe}(011)$ grows epitaxially on FeRh-Ir(001) plane (Fig. 1). The corresponding NiFe(022) XRD peak was observable for $t(\text{NiFe}) > 1.6 \text{ nm}$.

III. MAGNETIC PROPERTIES

Magnetic properties of FeRh-Ir and NiFe/FeRh-Ir systems were studied using a vibrating sample magnetometer, at temperatures ranging from 300 to 600 K . All measurements were performed with an in-plane geometry ($\mathbf{H} \parallel \text{MgO}[100]$, $\text{FeRh-Ir}[110]$).

At room temperature, we observed no appreciable FM behavior of the FeRh-Ir films. The AF-FM transition occurs in the temperature range from 400 to 500 K .¹² The magnetization change with temperature¹² is not steplike, typical for bulk alloys,^{11,14} however, it is much steeper than those reported earlier for FeRh films by other authors.⁷⁻⁹ This is true even for very thin (15 nm) FeRh-Ir layers.

Hysteresis loops of $\text{NiFe}(110)$ films grown on FeRh-Ir exhibit considerably large coercive field H_c . On the other hand, we detected no shift of the loop which is typical for FM layers exchange coupled with Mn-based antiferromagnets,¹⁵ even after field cooling from 600 K under $H=20 \text{ kOe}$. At a fixed NiFe thickness, the coercivity H_c is nearly constant for FeRh-Ir thicknesses $t_{\text{FeRh-Ir}} > 18 \text{ nm}$. Below this value, H_c is approximately proportional to $t_{\text{FeRh-Ir}}$. Results of STM observations show that this behavior is most probably related to the morphology changes (decrease of the terrace size and appearance of holes in the film) in the low FeRh-Ir thickness limit of continuous FeRh-Ir layer. Thus, for the following studies we have chosen

FIG. 4. Room temperature hysteresis loop in the NiFe(2.5 nm)/FeRh-Ir(22 nm)/MgO(001) structure.

$t_{\text{FeRh-Ir}}=22$ nm, which may be the optimum thickness for applications of these antiferromagnetic layers in spin valves.

We also studied the effect of permalloy layer thickness on H_c (Fig. 3). For ultrathin NiFe layers, H_c increases with t_{NiFe} and reaches a maximum of about 810 Oe at $t_{\text{NiFe}}=2.7$ nm. At and above this thickness, the NiFe layers exhibit square hysteresis loop (Fig. 4). For larger NiFe thicknesses, H_c decreases, obeying approximately the $H_c \sim 1/t_{\text{NiFe}}$ law (see inset of Fig. 3). Such a variation with t_{NiFe} suggests that the origin of the large coercive field occurs at the NiFe/FeRh-Ir interface. This explanation is also supported by the fact that samples with better FeRh-Ir surface morphology show larger H_c .

IV. CONCLUSIONS

We have prepared single crystal $\text{FeRh}_{0.95}\text{Ir}_{0.05}$ ordered alloy films with CsCl (B2) structure. $\text{Ni}_{0.81}\text{Fe}_{0.19}(011)$ layers were deposited on the atomically flat FeRh-Ir terraces. In-plane magnetization loops exhibit large coercive fields, H_c , which reached a maximum of 810 Oe for $t_{\text{FeRh-Ir}}=22$ nm and $t_{\text{NiFe}}=2.7$ nm. The observed H_c dependence on $(1/t_{\text{NiFe}})$ at

larger NiFe thickness suggests that those considerably large coercive fields originate from a magnetic interaction at NiFe/FeRh-Ir interface. The large H_c could be used as a pinning force in a spin valve structure. To understand the mechanism of the interface interaction and the effect of morphology on magnetic properties of these structures, further research is in progress.

$\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}\{100\}$ epitaxial films, ranging in thickness from 70 to 1200 Å, were grown by solid-source metal-organic chemical vapor deposition. The exchange field for 45 Å $\text{Ni}_{80}\text{Fe}_{20}$ on $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ films reached 250 Oe at 200 Å $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ and then stayed almost constant with increasing thickness of $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$. Furthermore, the coercivity for those films is only 55 Oe. The high exchange field and the low coercivity are attributable to the high in-plane anisotropy of $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}\{100\}$ and the uncompensated spins in the interface of $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}/\text{Ni}_{80}\text{Fe}_{20}$. The blocking temperature of these films is 180 °C, lower than that of $\text{NiO}/\text{Ni}_{80}\text{Fe}_{20}$ (~220 °C). The reduction of the blocking temperature may result from local Fe–O–Fe or Fe–O–Ni bonding, which loses the superexchange interaction at a lower temperature than the blocking temperature of NiO .

I. INTRODUCTION

The anisotropic exchange interaction between NiO and $\text{Ni}_{80}\text{Fe}_{20}$ has been extensively studied.^{1–3} Although NiO has shown potential as a biasing material, the low anisotropy of NiO , resulting in a relatively low exchange field (H_e) and a high coercivity (H_c) of $\text{NiO}/\text{Ni}_{80}\text{Fe}_{20}$ systems,² limits its use as a biasing layer in spin valves.³ To increase exchange fields, previous attempts were made to change the anisotropy of NiO by doping with cobalt (Co^{+2})¹ and strontium (Sr^{+2}).² In recent work,⁴ we demonstrated the growth of $\{111\}$ epitaxial and polycrystalline Fe-doped NiO by solid-source metal-organic chemical vapor deposition (MOCVD), and showed enhancement of H_e for the Fe content up to 18 at. %. Because the spin-compensated nature of $\text{NiO}\{100\}$ planes⁵ contrasts with the spin-uncompensated nature of $\{111\}$ planes, it would be interesting to examine the effect of Fe doping on the epitaxial $\text{NiO}\{100\}$ films. Because 18 at. % Fe doping showed maximum H_e in polycrystalline and $\{111\}$ Fe-doped NiO systems, we have deposited 18% Fe-doped $\text{NiO}\{100\}$ films of various thicknesses on $\text{MgO}\{100\}$, and report here the variation of the exchange field and the coercivity with the oxide thickness for the $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}\{100\}/\text{Ni}_{80}\text{Fe}_{20}$ system.

II. EXPERIMENTAL PROCEDURES

Fe-doped NiO films ranging in thickness from 70 to 1200 Å were grown on $1\text{ cm} \times 1\text{ cm} \times 0.5\text{ mm}$ $\text{MgO}\{100\}$ substrates, using a solid-source MOCVD technique at a growth temperature of about 510 °C. The Fe content, fixed at 18 at. %, was controlled by the mixing ratio of solid-source $\text{Fe}(\text{TMHD})_3$ to $\text{Ni}(\text{TMHD})_2$ (TMHD: tetra-methyl-heptanedionate). $\text{Ni}_{80}\text{Fe}_{20}$ films 45 Å thick were deposited on the Fe-doped NiO films by dc magnetron sputtering in the pres-

ence of a magnetic field of 70 Oe. The surface of the oxide film was cleaned by ion beam bombardment before the deposition of $\text{Ni}_{80}\text{Fe}_{20}$, and 50 Å of Ta was used as a capping layer. The $\text{Ni}_{80}\text{Fe}_{20}$ and Ta films were deposited at room temperature. The microstructure and phases were identified by transmission electron microscopy (TEM). Since the anisotropic exchange is quite surface sensitive, we took the reflection high energy electron diffraction (RHEED) patterns on the oxide surface to examine the surface symmetry. Electron probe microanalysis (EPMA) was used to determine the average chemical compositions and the thicknesses of the films. The distribution of Fe dopants was measured by energy dispersive x-ray spectroscopy (EDX) attached to TEM. The valence states of Fe and Ni were determined by x-ray photoelectron spectroscopy (XPS). The surface roughness was estimated by atomic force microscopy (AFM). The hysteresis loops were taken using the magneto-optical Kerr effect (MOKE), and the exchange field was determined by the shift of the loops. High-temperature hysteresis loops were measured under pressures less than 2×10^{-6} Torr.

III. RESULTS

The atomic ratio of $\text{Fe}/(\text{Fe}+\text{Ni})$ was 18% measured with EPMA. In addition, the XPS chemical shifts of $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ showed that the dominant valence state of Fe and Ni was +2. Figure 1 shows the high resolution cross-sectional TEM images of the sample $\text{MgO}\{100\}/950\text{ Å}\text{ Ni}_{0.82}\text{Fe}_{0.18}\text{O}/45\text{ Å}\text{ Ni}_{80}\text{Fe}_{20}/50\text{ Å}\text{ Ta}$. The continuous lattice fringes from MgO to $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ indicated a high-quality epitaxial growth of $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}\{100\}$ on $\text{MgO}\{100\}$. In addition, no extra spots found in the diffraction pattern indicated that no second phases formed, and that the majority of Fe dopants dissolved into the NiO matrix. From the line scan of EDX, we found the Fe dopants uniformly distributed into NiO matrix. The RHEED patterns of the $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ surface consist of Kiku-

^{a)}Electronic mail: chih.lai@readrite.com

FIG. 1. The high resolution cross-sectional TEM image of MgO {100}/950 Å $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ /45 Å $\text{Ni}_{80}\text{Fe}_{20}$ /50 Å Ta. The bottom-left corner is the lattice image of the interface between MgO {100} and $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$.

chi lines and intensity-modulated diffraction streaks, indicating that the $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ film is single crystalline, however, not perfectly smooth. Thus, transmission-type diffraction patterns modulate the streaks and reveal the surface symmetry: fourfold and {100} aligned. The root-mean-square (rms) roughness on the surface of 450 Å $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ was 8.5 Å, measured with AFM.

The hysteresis loop of 45 Å $\text{Ni}_{80}\text{Fe}_{20}$ on 450 Å $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ {001} along the easy axis is shown in Fig. 2. The H_e and H_c are 255 and 55 Oe, respectively. Comparing with $\text{Ni}_{80}\text{Fe}_{20}$ on epitaxial MOCVD NiO {001},⁶ whose H_e and H_c are 40 and 250 Oe, 18% Fe doping in NiO {001} increases H_e as much as 6 times! This high ratio of H_e/H_c and high H_e are also different from the results reported in the pure polycrystalline NiO system,^{1,7} which typically has a H_e/H_c ratio of less than 2, and H_e smaller than 220 Oe. The interfacial coupling energy $K_e = H_e \times M_s \times t_f$ (M_s and t_f are the saturation magnetization and the thickness of $\text{Ni}_{80}\text{Fe}_{20}$, respectively) is ~ 0.09 erg/cm².

Figure 3 shows the changes in H_e and H_c (measured along the easy axis) of 45 Å $\text{Ni}_{80}\text{Fe}_{20}$ on $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ {001} films as the thickness varies from 70 to 1200 Å. H_e appeared at oxide thickness $t_{af} = 140$ Å, reached to 250 Oe at $t_{af} = 200$ Å, and then H_e remained almost constant

FIG. 2. Hysteresis loop of 45 Å $\text{Ni}_{80}\text{Fe}_{20}$ on 450 Å $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ {001}. The field was applied along the easy axis.

FIG. 3. AF thickness dependence (t_{af}) of the exchange field (H_e) and the coercivity (H_c) for 45 Å $\text{Ni}_{80}\text{Fe}_{20}$ on 450 Å $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ {001} films.

(~ 250 Oe) with increasing thickness of $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$. The result is in contrast to that in the polycrystalline pure NiO systems,^{3,7} which show that a larger thickness ($t_{af} > 300$ Å) is needed to reach a saturated value of H_e ($H_e < 220$ Oe for 45 Å NiFe).

In spite of the enhancement of the exchange field in 18% Fe-doped {100} films, the blocking temperature T_b —the temperature at which H_e goes to zero—of these epitaxial {100} films was 180 °C, lower than that of pure NiO^{1,3} ($T_b \sim 200$ –220 °C). This result is similar to those of 18% Fe-doped polycrystalline and epitaxial {111} NiO films.⁴ The temperature dependence of H_e for 45 Å $\text{Ni}_{80}\text{Fe}_{20}$ on 450 Å $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ {001} film is shown in Fig. 4. Note that the H_e is always larger than H_c until the temperature reaches T_b .

IV. DISCUSSION

At temperatures above $T_N = 523$ K, the Néel temperature of NiO, NiO is paramagnetic and crystal structure is cubic rock salt.⁵ Below T_N , the antiferromagnetic ordering results in a slight rhombohedral deformation of crystal, which consists of a contraction of the original unit cell along one of the {111} axes. The spins of NiO below T_N are arrayed in ferromagnetic sheets which are parallel to {111}, and the direction

FIG. 4. Temperature dependence of the exchange field (H_e) and the coercivity (H_c) for 45 Å $\text{Ni}_{80}\text{Fe}_{20}$ on 450 Å $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ {001} films.

of magnetization in neighboring planes is reversed;⁵ therefore, for {100} planes, spin compensation occurs since alternate spins are antiferromagnetically ordered in the planes. Ideally, if the $\text{Ni}_{80}\text{Fe}_{20}$ film coupled to a single-domain NiO {100} with an atomic flat interface, the exchange field should approach to zero. In reality, because of the interface roughness and finite-size multidomains, a nonzero H_e exists,^{2,8} but the value is smaller than that of $\text{Ni}_{80}\text{Fe}_{20}$ on polycrystalline NiO . In contrast to the NiO {100} case, $\text{Ni}_{80}\text{Fe}_{20}$ coupled to $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ {100} shows high H_e . The surface roughness of MOCVD NiO and $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ are similar, which eliminates the effect of interface roughness on H_e . From the results of EDX and XPS, we know that the Fe dopants distribute uniformly in the NiO matrix with valence state +2. Roth has done neutron diffraction to determine the magnetic structure of NiO and FeO ,⁵ and showed that the average moments per site of nickel and iron in NiO and FeO are $2\mu_B$ and $3.32\mu_B$, respectively. The uneven moments of Ni and Fe may increase the degree of uncompensation in the interface, which may contribute to the high nonzero value of H_e .

Two requirements are needed for achieving high exchange fields: an uncompensated interfacial spin configuration of an antiferromagnet (AF), and a large anisotropy of the AF to make the spins of the AF remain pinned during the magnetization reversal of ferromagnets. The most obvious way to have an uncompensated interface in NiO is to deposit ferromagnets on NiO {111}. In our previous work,^{4,6} we reported that the $\text{Ni}_{80}\text{Fe}_{20}$ on NiO {111} or on $\text{Ni}_x\text{Fe}_{1-x}\text{O}$ {111} showed large coercivities and relatively low exchange fields. We found that the contraction axis was perpendicular to interfaces,⁹ i.e., all spins lie within {111} planes parallel to the interface. Because in-plane anisotropy within those {111} planes is weak, the exchange field is low. On the other hand, NiO {100} planes have a compensated nature, but {100} planes are 54.7° away from the contraction axis; therefore, the field needed to rotate the spins within {100} planes is higher than that in {111}, resulting in a higher in-plane anisotropy. From the previous discussion, since Fe dopants may increase the degree of uncompensation, $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ {100} satisfies both requirements for high H_e . Furthermore, FeO is known to have considerably higher magnetic anisotropy than NiO (Ref. 10) because the orbital degeneracy is not completely removed in FeO . The dissolved Fe atoms can participate in local Fe–O bonding and increase the anisotropy of NiO . In addition, high-quality epitaxial NiO films may form large magnetic domains, which may result in small H_e .¹¹ The Fe dopants can introduce stress and defects into NiO matrix and suppress the formation of large domains, and further enhance the H_e .

The high anisotropy of $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ {100} is also reflected on a small thickness needed for high H_e and on a low coercivity of $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ {100}/ $\text{Ni}_{80}\text{Fe}_{20}$. As the thickness of

$\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ increases, the volume anisotropy energy of $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ ($K_{af} \times t_{af} \times \text{area of interface}$, K_{af} = anisotropy energy per unit volume of $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$) increases. The thickness needed for high H_e is the thickness at which the volume anisotropy energy of $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ is large enough to pin its spins during the field reversal; therefore, larger anisotropy in the oxide (K_{af}) means smaller thickness (t_{af}) needed to reach high H_e . From our previous study,² we found that the main source of coercivity in the $\text{NiO}/\text{Ni}_{80}\text{Fe}_{20}$ system is the irreversible rotation of spins in NiO due to the low anisotropy of NiO . Consequently, when the anisotropy of NiO is increased by Fe doping, the coercivity is significantly reduced.

In spite of the enhancement of H_e , the blocking temperature of $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ was reduced. This may be due to the local Fe–O–Fe or Fe–O–Ni bonding, which loses the superexchange interaction at a lower temperature than the Ni–O–Ni bonding does. This is consistent with the low Néel temperature (198 K) of FeO .

V. CONCLUSIONS

We have observed a high exchange field (250 Oe) and a low coercivity (55 Oe) for 45 Å $\text{Ni}_{80}\text{Fe}_{20}$ on the $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ {100} films with thickness larger than 200 Å. The increase of H_e can be attributed to the high in-plane anisotropy of $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ {100} and the uncompensated spin configuration in the interface due to the Fe doping. The high anisotropy of $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}$ also results in a low coercivity and a small thickness needed to reach a high H_e . A reduction of the blocking temperature ($T_b = 180^\circ\text{C}$) of the $\text{Ni}_{0.82}\text{Fe}_{0.18}\text{O}/\text{Ni}_{80}\text{Fe}_{20}$ system possibly relates to the local Fe–O–Fe or Fe–O–Ni bonding, which loses the superexchange interaction at a temperature lower than the blocking temperature of NiO .

Temperature dependence of ferromagnetic resonance as induced by NiO pinning layers

P. Lubitz,^{a)} J. J. Krebs, M. M. Miller, and Shufan Cheng
Naval Research Laboratory, Washington, DC 20375

Ferromagnetic resonance (FMR) experiments have been conducted near 9.5 GHz on permalloy (Py) thin films which are components of spin valves and related structures. These so-called giant magnetoresistance structures often use antiferromagnetic NiO to achieve pinning of one magnetic layer. Magnetic anisotropies acting on these pinned layers were deduced by observing their resonances for fields perpendicular to and in the sample plane. We used data taken from 4 to 600 K to identify potential mechanisms of pinning, anisotropy, and linewidth. The anisotropic exchange pinning and an isotropic downward FMR shift vanish at a blocking temperature well below the bulk Néel temperature of NiO. The strong temperature dependencies of the isotropic shift and linewidth may reflect the presence of different spin pinning subsystems and the different time scales of the FMR and low frequency or static measurements. [S0021-8979(98)30211-X]

INTRODUCTION

Antiferromagnetic (AF) and spin glass systems in intimate contact with thin ferromagnetic films have been shown to produce large shifts in the position of the ferromagnetic resonance lines.¹ The ferromagnet is strongly exchange coupled to an ordered spin system with small net moment, and therefore experiences the constraints responsible for the ordering in that system—in effect, the ferromagnet gives us an external “handle” on the adjacent low moment system. Reported results¹ for FMR on such systems have shown a variety of temperature dependencies of the line shifts (e.g., $\alpha \exp(-T/T_0)$ for spin glasses but with more abrupt onsets for thin NiO and CoO). Also conspicuous is the nearly isotropic nature of the shifts, i.e., all directions appear “easy.” Such shifts apparently are independent not only of orientation but also of measurement frequency.^{1,2}

Using a system in wide use, Py (nominally 80 at. % Ni, 20% Fe) biased by NiO, we have conducted FMR measurements at about 9.5 GHz for temperatures from 4 to 600 K and for a variety of orientations. This system has been studied extensively by mostly static B–H loop, Kerr, and magnetoresistance measurements.³ Predictions of exchange coupling in FM/AF systems have been made⁴ but the results depend strongly on grain size and orientation, surface roughness, and magnetization process.

We determined the isotropic and anisotropic shifts and the linewidths. From their particular temperature dependencies, we make inferences as to the magnetic configurations which may be responsible for the phenomena observed.

EXPERIMENT

Spin valve structures and subcomponents were made by dc magnetron sputtering without cooling, i.e., at slightly above 300 K. For this paper, all Py and Cu layers were nominally 45 Å thick, NiO layers were 1000 Å, and all were polycrystalline. The structures were deposited on polished Si

wafers having a native oxide surface. After deposition of successive layers of Py, Cu, and Py again, in a magnetic field sufficient to align the Py layers, the NiO layer was formed by reactive sputtering of Ni. Separate films of Si/Py/Cu, Si/Cu/Py/NiO, and Si/Cu/Py/Cu were also made. All of these configurations have low roughness metal layers, a few angstroms rms, as determined by atomic force microscope and have low linewidths and coercivities for the unpinned magnetic layers.

FMR data were taken with a Bruker ECS9 system operating at about 9.46 GHz with temperature control provided by N₂ (100–600 K) or He (4–300 K) gas flow systems. Magnetoresistance and vibrating sample magnetometry data were also obtained on the samples at room temperature.

RESULTS

The as-made Py films with NiO overlayers have a static exchange bias field of about 100 Oe. Figure 1 shows in-plane FMR data illustrating several features: (a) low-field structure related to magnetoresistance changes, (b) a broad temperature sensitive absorption line arising from the Py layer adja-

FIG. 1. FMR spectra of a spin valve with the applied field along the hard in-plane direction showing the switching of the pinned Py at low fields, and the pinned and free Py resonances (arrows).

FIG. 2. $H_{e,iso}$ and $H_{e,aniso}$ as functions of temperature as derived from in-plane FMR data.

cent to NiO, and (c) a narrower line with weak angular and temperature dependence arising from the unpinned Py layer. The pinned Py resonance line moves downward rapidly in field position on cooling while the low field structures move upward more slowly, largely because the coercivity of the pinned layer increases.

It is difficult to determine the magnitude of exchange induced shifts absolutely. Films of the same thickness with different interface materials² generally have different moments. We considered use of the pinned line above the T_N of NiO (523 K) as a reference. However, its moment was found to change irreversibly near T_N because of diffusion of Cu into Py above 200 °C. Therefore we discuss only data up to 450 K and arbitrarily assign the position of the resonance at that temperature as a reference, H_{ref} .

We characterize the exchange effects for in-plane data by means of an anisotropic exchange field $H_{e,aniso}$ and an isotropic exchange shift $H_{e,iso}$. For the anisotropic effects, we take $H_{e,aniso} = H_r(\text{hard}) - H_r(\text{easy})$ so a reference is irrelevant. Here $H_r(\text{easy})$ is the resonance field when H is along the exchange bias favored direction established by the field during Py deposition while $H_r(\text{hard})$ is the corresponding field for H rotated by 180°. For the isotropic component, we take $H_{e,iso} = H_{ref} - [H_r(\text{easy}) + H_r(\text{hard})]/2$.

The $H_{e,iso}$ and $H_{e,aniso}$ data calculated in this way are shown in Fig. 2 as derived from in-plane FMR. For temperatures between 350 and 150 K, $H_{e,aniso}$ is essentially constant. At higher temperatures, this anisotropy disappears in a narrow temperature range, at essentially the same temperature at which the B-H loop shift (the usual exchange bias field) goes to zero. Since this is well below the bulk T_N , we ascribe this to the blocking transition as described by Carey *et al.*³ (only for the “as-deposited” condition did their exchange field disappear near 380 K; for samples which contain thin layers of CoO, they were able to increase the blocking temperature to near T_N by field cooling, which we are not able to duplicate).

Below about 150 K and for applied fields in the film plane, the pinned Py FMR lines fall below the field values necessary to saturate the Py (below zero field for the easy direction) and no easily interpreted spectra are seen. By taking data in the perpendicular orientation we were able to follow the increase in field shift down to 4 K. If we account

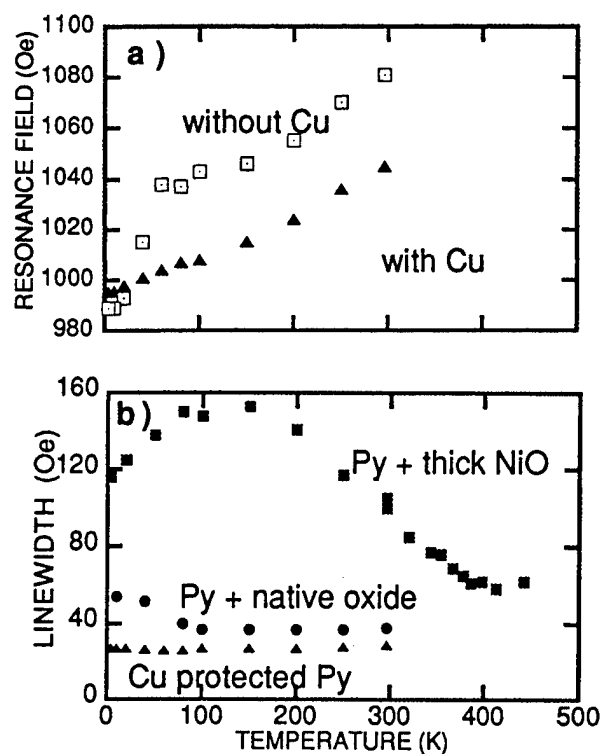

FIG. 3. (a) FMR fields for nominally unpinned Py with and without 45 Å Cu protective layers and (b) effect of Cu protective layers, native oxide, and thick NiO on temperature dependence of FMR linewidths of adjacent Py.

for the temperature dependence of M , the shift tracks that of the in-plane data over the common temperature region. This trend continues even down to 4 K if the sample is not reoriented during the cooling. However, below about 150 K, the spectra become hysteretic and additional lines appear which must be addressed in a later paper.

Near 300 K, linewidths of the pinned Py (Fig. 3) are about 100 Oe for all orientations and show a moderate increase to about 160 Oe near 150 K; for fields perpendicular to the film plane, the lines narrow to near 100 Oe at 4 K, if the sample is not reoriented. To determine what part of these effects is intrinsic to our Py, we also made and measured Py layers with Cu capped and native oxide surfaces. Py layers with native oxide surfaces have widths near 40 Oe at 300 K and these broaden at low temperatures (Patton⁵ reported somewhat similar results for oxidized Py). Cu protected Py has linewidths less than 30 Oe which narrow slightly with cooling.

In measuring nominally unpinned reference Py samples, we have found that they also generally show small isotropic (only downward) shifts, but these are significant only for temperatures below 50 K, see Fig. 3. The shift shows no freezing-in (i.e., it is the same after rotating 180° even at 4 K) and increases with decreasing temperature even near 4 K; the size of the shift varies inversely with Py thickness. These shifts bear a strong resemblance to those observed by Takano *et al.*⁴ We found that Py films having either a native oxide layer or deposited on the native oxide of Si have comparable shifts but Py films which have Cu on both surfaces show a much reduced effect.

DISCUSSION AND CONCLUSIONS

The temperature dependence of the Py FMR line shifts associated with NiO adjacent layers reveal a variety of distinctive phenomena. First, nominally static exchange fields $H_{e,\text{aniso}}$, which act like unidirectional fields and have the same magnitude as the exchange shifts of hysteresis loops³ (also reported² in FMR near room temperature), are clearly present. These have only a weak temperature dependence up to near the blocking temperature which in our samples is generally about 380 K (well below T_N), above which they become negligible. The linewidth decreases moderately with increasing temperature until above the blocking temperature, perhaps indicating that the mechanism responsible for the anisotropic shifts has spatial variations which broaden the line. In order to not be narrowed by the exchange interaction in the Py layer, these variations must have a scale of at least a few hundred angstroms, i.e., a Py "wall" width, $W = \sqrt{A/\Delta H_k M}$, where ΔH_k is a spatial variation of the exchange anisotropy, presumed to be about 100 Oe. The remaining width relative to unpinned Py may be related to the variable oxidation states of the surface species, which can allow additional relaxation mechanisms, especially since Fe is present.⁵ Note that the presence of even a thin native oxide on Py adds a significant width. (Our earlier work¹ showed that thin Cu or Ni surface layers on Fe polycrystalline films reduced the linewidths to the lowest values reported for metal films, 15 Oe., implicating the role of iron oxides in this line broadening.)

The origin of the isotropic and strongly temperature dependent fields $H_{e,\text{iso}}$ sensed by the FMR from about 150 K (and possibly much lower) up to the vicinity of T_N is much less certain. Earlier reports of isotropic shifts considered a spin-glass phase as the probable source.¹ It is tempting to postulate additional spin systems, e.g., small grain regions in the NiO at the interface with Py. Indeed, Chopra,⁶ using TEM, observed a fraction of small surface grains in his NiO biased spin valves. This conjecture is supported further by the absence of strong line broadening as $H_{e,\text{iso}}$ increases, implying that the mechanism arises from parts of the NiO with less than about 100 Å lateral extent.

The isotropic shifts indicate spin subsystems which can follow the external field rather than being frozen into the sample. One such shift [Fig. 3(a)], seen at low temperatures in nominally unpinned Py, can be attributed to a surface-oxide spin system since Cu capping eliminates it; this shift has the same temperature dependence and magnitude as a surface induced field reported by Takano *et al.*⁴ for CoO.

That effect has a frozen-in or remanent aspect which is much reduced for small applied fields. Since that field was not strongly frozen-in, even for CoO which has very strong single ion anisotropy, it is not surprising that our native oxide layers, which we presume to be mainly NiO with a much smaller local anisotropy, lack any memory at 4 K. The broadening accompanying this shift is likely to represent a true magnetic relaxation rather than a large scale inhomogeneity.⁵

Neél's analysis⁷ of the time dependence of the response of small magnetic particles predicts a response time $\tau = \tau_0 \exp(E/kT)$ where E is an energy barrier (e.g., magnetic anisotropy $K \times \text{volume}$) and τ_0 is a characteristic precession time (low microwave frequency). Hence, for small AF grains, the magnetic configuration can change rapidly for temperatures above E/k , but the configuration cannot evolve as fast as our microwave frequency. Thus, in the FMR experiment, the exchange anisotropy sensed, and thus the resonance field, are determined by a local energy minimum which appears static, but which easily follows reorientations of the Py moment and therefore does not appear as an anisotropic bias field. On cooling, a larger fraction of grains becomes aligned relative to the Py at any instant, giving a larger shift.

Much stronger exchange fields are sensed in FMR at low temperatures than are indicated by static experiments. Identification of a spin subsystem responsible for the large isotropic shifts will require more detailed analysis of the microstructure. Our data place strong constraints on the lateral size of the features, which impact the linewidth, on their anisotropy energy and volume, which determine freezing temperatures, and on the fraction of surface spins involved, which determines the size of the line shifts.⁴

Dependence of exchange coupling on antiferromagnetic layer thickness in NiFe/CoO bilayers

T. Ambrose^{a)} and C. L. Chien

Department of Physics and Astronomy, The Johns Hopkins University, Baltimore, Maryland 21218

A systematic study of the dependence of exchange coupling in NiFe/CoO bilayers on CoO layer thickness t_{AF} from 5 to 500 Å has been made. For large CoO thicknesses ($t_{AF} > 100$ Å), the exchange field varies as $1/t_{AF}$, whereas for small CoO thicknesses ($t_{AF} < 100$ Å), finite-size scaling of the Néel temperature T_N and also the blocking temperature T_B dominate. © 1998 American Institute of Physics. [S0021-8979(98)52811-3]

The exchange coupling between a ferromagnet (FM) and an antiferromagnet (AF) displays a rich variety of phenomena.¹ When a FM/AF bilayer thin film is field cooled across the AF Néel temperature (T_N), the hysteresis loop of the FM is now shifted or biased away from the origin. This shift, known as the exchange field (H_E), can be several hundreds Oe in size. The AF must possess sufficient anisotropy to withstand switching of the FM magnetization. The exchange field decreases with temperature and vanishes at a temperature termed the blocking temperature T_B , which is less than T_N of the AF layer. The anisotropy of the AF must decrease to zero at T_N . Near and below T_N , the anisotropy of the AF eventually becomes too weak to maintain its spin structure during the hysteresis cycle resulting in no exchange field.

Exchange biasing is important for applications in the spin-valve devices,² although the origin of this coupling remains unclear. Some of the important questions concerning exchange biasing include the relative spin orientation of the FM and AF layers, and the interaction between them. It has been well established that H_E varies inversely with the FM layer thickness.^{3,4} This demonstrates that the exchange coupling is transmitted across the FM/AF interface. It has been widely assumed that this exchange coupling is a short-range interaction occurring only at the interface, although some new results suggest otherwise.⁵ In this work, we address the dependence of exchange bias on the AF layer thickness.

There have been previous studies on the effect of the AF layer thickness on the exchange coupling strength in NiFe/FeMn^{6,7} in NiFe/NiO⁸ and in CoO/NiFe⁹ bilayers. In these works, both the exchange fields and blocking temperatures were observed to correlate with the AF layer thickness in some manner. Unfortunately, most of these measurements were not made at sufficiently low temperature to conclusively determine the dependence on the AF layer thickness. Recently, a study of the AF layer thickness dependence on H_E was made in Fe₃O₄/CoO bilayers,¹⁰ where the exchange field was measured to low temperatures. With the few samples, the values of H_E and the blocking temperature were observed to scale with the CoO thickness, but a clear relationship between the exchange field and the AF layer thickness was not determined.

In this work, we have determined the relationship between the AF layer thickness and the exchange bias using NiFe/CoO bilayers with a fixed NiFe layer and various CoO thicknesses from 5 to 500 Å. There are two qualitatively different behaviors of the dependence on the AF layer thickness t_{AF} . For $t_{AF} > 100$ Å, where T_N remains unchanged, H_E is found to vary as $1/t_{AF}$. For $t_{AF} < 100$ Å, the effect is due to finite-size scaling of T_N of very thin layers, and the results are in good agreement with the susceptibility measurements using CoO/SiO₂ multilayers.¹¹

To examine the AF layer thickness dependence on the exchange field, the NiFe/CoO system was chosen, involving a well-known AF insulator CoO with $T_N = 292$ K and permalloy (NiFe = Ni₈₁Fe₁₉) useful for many device applications. To carefully examine the AF layer thickness dependence, the bilayers in this study were taken from one large sample of a 300 Å film of NiFe grown on a wedge layer (5–500 Å) of CoO, which was grown on 300 Å Cu. The CoO wedge film allows many samples that were fabricated at the same time and under the same deposition conditions with CoO thickness being the only parameter. The NiFe was deposited in a magnetic field to induce an uniaxial anisotropy. We used the geometry of FM layer grown on top of the AF layer, so that the exchange field would saturate at low temperatures to reveal its dependence on the AF layer thickness.¹²

In Fig. 1(a), the temperature dependence of the exchange field of some representative samples with varying CoO layer thickness from 75 to 457 Å are shown. As expected, a plateau in the exchange field is observed at low temperatures whose value is intrinsic, for this bilayer geometry, to a specific AF layer thickness. The results for $t_{AF} > 100$ Å clearly show an increase in the exchange field as the CoO thickness is reduced. The values of H_E vanish essentially at 291 K, the Néel temperature of bulk CoO. As shown in Fig. 1(b), the coercivity (H_C) has a quasilinear temperature dependence, decreasing to the intrinsic H_C of permalloy at approximately 291 K. The exchange fields at low temperatures, represented by the values at 80 K are shown as a function of the CoO layer thickness in Fig. 2. The results can be best described by $1/t_{AF}$ shown as the dashed curve. It should be noted that this relation holds only at low temperature where H_E is not temperature dependent. At a high temperature, where H_E has a strong temperature dependence, the H_E values do not give

meaningful thickness dependence. For example, if one uses the exchange field values at 250 K, one would give a totally different thickness dependence from that at 80 K, as shown in Fig. 2. These results clearly demonstrate the dependence of exchange coupling on t_{AF} in the thickness range of $t_{AF} > 100$ Å, where T_N remains unchanged.

The results in Fig. 2 are rather unexpected and significant because it illustrates that the exchange coupling in a FM/AF bilayer involves more than just the interfacial spins in the FM and AF layers. To elaborate the argument, consider the ideal interface model as originally suggested by

FIG. 2. The values of exchange field H_E measured at 80 and 250 K for 300 Å NiFe/ x Å CoO/300 Å Cu as a function of the CoO layer thickness. The dashed line for the data at 80 K is $1/t_{AF}$.

Meiklejohn and Bean,¹ where the exchange coupling between neighboring spins at the FM/AF interface produces an exchange field of the form

$$H_E = \frac{nJS_{AF} \cdot S_{FM}}{M_{FM}t_{FM}}, \quad (1)$$

where S_{FM} and S_{AF} are the spins of the magnetic moments in the FM and AF layers at the interface, M_{FM} and t_{FM} are the magnetization and layer thickness of the FM, respectively, J is the spin-spin interaction strength between S_{FM} and S_{AF} and n is the number of interactions per unit area with strength J . Since only the interfacial FM and AF spins are assumed to be involved, the thickness of the AF layer does not appear at all. The very fact that H_E has a $1/t_{AF}$ dependence indicates that this simple model and Eq. (1) require modifications. The spin structure and the domain walls of the AF layer ultimately influence the exchange field as suggested by the recent micromagnetics calculations by Malozemoff,¹³ Mauri,¹⁴ and Koon.¹⁵

In Fig. 2, the values of H_E for AF layers smaller than 100 Å have not been included because these results are qualitatively different from those of the thicker layers, and also that their H_E values do not saturate at 80 K. These features are illustrated in Fig. 3 for CoO thicknesses spanning from 10 to 256 Å. While the blocking temperature T_B of samples with $t_{AF} > 100$ Å remains at the bulk value, T_B of the thinner samples progressively decreases with t_{AF} . As the layer thickness is reduced below 100 Å, one observes finite-size effects of T_N ,^{10,11} which is followed by T_B . It is interesting to compare the finite-size effects of T_B measured from exchange bias in NiFe/CoO bilayers, and the finite-size effects of T_N measured from dc susceptibility measurements using CoO/SiO₂ multilayers. In Fig. 4 the blocking temperatures T_B (solid squares) obtained from the exchange field temperature dependence in Fig. 3 are compared with the Néel temperatures T_N measured by susceptibility in CoO/SiO₂ multilayers.¹¹ Both sets of data are in excellent agreement. At each thickness, the blocking temperature T_B is slightly

FIG. 4. Blocking temperature T_B (solid squares) of 300 Å NiFe/ x Å CoO/300 Å Cu and Néel temperature T_N (open circles) of CoO/SiO₂ multilayers, as a function of the CoO layer thickness. The solid line is the finite-size scaling relation taken from Ref. 11.

below T_N . This comparison also shows that the dependence of exchange bias in the thickness range of $t_{AF} < 100$ Å is largely effected by finite-size scaling of the AF Néel temperature.

To summarize, we have observed dependence of exchange bias on the antiferromagnetic layer thickness t_{AF} . For small values of t_{AF} (< 100 Å), this is mainly caused by the finite-size scaling of T_N , whose value always lies slightly higher than that of the blocking temperature T_B . For larger values of t_{AF} (> 100 Å), the exchange field has been

shown to scale inversely with t_{AF} . This suggests that the simple picture of interfacial coupling between the FM and AF spins be modified to include the spin structure and the domain structure within the AF layer.

The Center for Micromagnetics and Information Technologies (MINT), Department of Electrical Engineering and Computer Science, University of Minnesota, Minneapolis, Minnesota 55455

In this study, the magnetic behavior of NiFe/NiO bilayers has been investigated. The relationship between the magnetic properties and interfacial interaction has been briefly discussed. Since magnetic properties of the bilayers are mainly determined by interfacial magnetic interaction, in this article, not only unidirectional interfacial anisotropy has been used to explain exchange field, H_{ex} ; also, for the first time, uniaxial interfacial anisotropy is introduced to describe interfacial interaction affecting the magnetic properties, especially coercivity H_c of the bilayers. In addition, a model is proposed to explain the magnetic behavior of the bilayers. The model has been tested by experiment. The experimental results are consistent with the model prediction, and this also confirms the assumption that the magnetization of the bilayer reverses by magnetic rotation. © 1998 American Institute of Physics. [S0021-8979(98)28411-8]

The exchange coupling between ferromagnetic (FM) and antiferromagnetic (AF) thin films has received increasing attention because it plays an important role in pinning the ferromagnetic layer in magnetoresistance (MR) heads or spin valves.¹ In recent years, although extensive works have been carried out to study various kinds of exchange coupled system,² the exchange coupling phenomenon is not yet fully understood. In particular, the simplest model predicts an exchange coupling H_{ex} typically 100 times greater than that observed in experiment. Recently, two models have been proposed by Mauri³ and Malozemoff⁴ to quantitatively explain this phenomenon. Both theoretical treatments of exchange coupling mechanism predict that the exchange field is proportional to $2(AK)^{1/2}$, where A and K are the exchange constant and anisotropy of the antiferromagnet, respectively. However, neither treatments can account for increased coercivities of the exchange coupled films. In this work, the relationship of magnetic properties with interfacial interaction has been explored, and a model for magnetic behavior of the FM/AF bilayers has been proposed and tested.

Magnetic behavior of the FM/AF bilayer is an interfacial phenomenon. It is believed that the magnetic properties of the bilayers are determined by interfacial interaction which is related to the spin distribution and arrangement at the interface. The interfacial magnetic interaction is strongly influenced by interfacial roughness and experimental conditions of depositing top FM layer.^{5,6} Interfacial roughness can provide more interfacial contact area and causes greater interfacial spin dispersion, leading to a higher coercivity of the bilayers.⁶ The interfacial interaction is also greatly dependent on experimental conditions.^{1,5} During sputtering, the incoming atoms with kinetic energy can disperse interfacial spins and promote interfacial interdiffusion. Lower sputtering pressure produces more incoming atoms with higher kinetic

energy which causes more atomic displacement and intermixing at the interface, which in turn enhances interfacial magnetic interaction, causing an increase of H_c . Similarly, substrate heating can promote interdiffusion which can enhance interfacial interaction, causing an increase of H_c . It is possible that, during sputtering deposition of NiFe on NiO, Fe atoms may replace some Ni atoms inside the NiO layer and on the interface, and O atoms in NiO may diffuse into NiFe layer to form a several Å thickness NiFeO interlayer and play a critical role in enhancing interfacial interaction between the NiO layer and NiFe layers. To verify this point, an interlayer of NiFeO was deposited by rf reactive sputtering of Ni_{0.80}Fe_{0.20} target to prepare a multilayer structure of NiFe(100 Å)/NiFeO(t)(400 Å)/Si. As shown in Table I, the 6 Å interlayer increases the interfacial magnetic interaction and causes a great increase of H_{ex} to 108 Oe and H_c to 58.5 Oe. However, with an increase of the NiFeO thickness, Both H_{ex} and H_c decrease. This is probably due to the larger thickness of NiFeO interlayer causing stronger dispersion of its spin configuration and reducing its antiferromagnetism. Furthermore, the evidence of interfacial magnetic interaction can also come from the fact that the magnetic properties of NiFe/NiO bilayers were observed measurement temperature dependent. H_{ex} decreases with increasing temperature and drops to zero at its blocking temperature T_B 175 °C.⁵ This is because, with an increase of temperature, the NiO spins are thermally fluctuating especially at the interface and reduce

FIG. 1. Schematic view of possible domain wall formed by rotating interfacial spins at antiferromagnet together with spins at ferromagnet: (a) without applying field; (b) with an applying field, the domain wall formed.

its antiferromagnetism gradually along with its exchange coupling to the NiFe layer. Similarly, H_c greatly decreases to 1.6 Oe at T_B due to interfacial magnetic interaction (exchange coupling) disappearing at T_B .

Since interfacial magnetic interaction is so important in determination of magnetic behavior of the bilayer, for the first time, the uniaxial interfacial anisotropy is introduced into the following model to explain the magnetic behavior of NiFe/NiO bilayers.

This model is based on two assumptions: (1) the exchange interaction $-2J\mathbf{S}_F \cdot \mathbf{S}_A$ at the interface is so strong that it bonds interfacial spins together to pin any domain wall motion of FM layer so that magnetization reversal of NiFe layer can only occur through magnetic rotation and it rotates together with interfacial spin at the antiferromagnet. As shown in Fig. 1, to minimize the energy, a domain wall could be formed in the antiferromagnet, which causes an unidirectional interfacial anisotropy and plays the role of determining the exchange coupling field, H_{ex} . (2) The uniaxial interfacial anisotropy K_I (energy per unit interface area) is introduced by applied field during deposition and is the same as the uniaxial anisotropy K_u (energy per unit volume) of NiFe layer. K_I and K_u have the same easy axis which is induced by the same applied field during deposition of the FM layer on AF layer. Both K_I and K_u are key factors to control the coercivity, H_c . Thus, when a magnetic field is applied along the easy axis, the total energy of bilayer system is

$$E = 2(AK)^{1/2}(1 - \cos \theta) + (K_I + K_u t) \sin^2 \theta - HMt \cos \theta. \quad (1)$$

The first term is the energy of domain wall formed by rotating interfacial spin at the surface of antiferromagnet. The second term is due to uniaxial anisotropy K_u of FM layer and uniaxial interfacial anisotropy K_I . The third term is Zeeman energy term. t is the thickness of FM layer and θ is the angle of magnetization away from easy axis.

From Eq. (1), by $\partial E / \partial \theta = 0$ and $\partial^2 E / \partial \theta^2 \geq 0$, it is easy to find out that the possible stable angles θ for magnetization are at $\theta = 0^\circ$ and $\theta = 180^\circ$. Figure 2 is $E-\theta$ curve. As we can see, without applying field, only one energy well is formed at $\theta = 0^\circ$, which is stable position for magnetization M . However, after applying a negative field H , the energy well at $\theta = 0^\circ$ becomes shallow and another energy well is formed at $\theta = 180^\circ$. At a certain field called nucleation field, the energy well at $\theta = 0^\circ$ disappears, meaning $\theta = 0^\circ$ is no longer a stable angle for magnetization. Therefore, magneti-

FIG. 2. $E-\theta$ curve (a) without applying field, $H=0$, only one energy well is formed at $\theta=0^\circ$, which is stable position for magnetization M ; (b) after applying a negative field H , the energy well at $\theta=0^\circ$ becomes shallow and another energy well is formed at $\theta=180^\circ$; (3) at a certain field called nucleation field, the energy well at $\theta=0^\circ$ disappears.

zation reversal should occur at the nucleation field, switching magnetization direction from $\theta=0^\circ$ to $\theta=180^\circ$, another energy stable position. Similarly, mathematically by $\partial E / \partial \theta = 0$ and $\partial^2 E / \partial \theta^2 = 0$, the nucleation field for magnetization reversal are given by

$$H_{0^\circ} = -2(AK)^{1/2}/Mt - 2(K_I + K_u t)/Mt, \quad (2)$$

$$H_{180^\circ} = 2(AK)^{1/2}/Mt - 2(K_I + K_u t)/Mt. \quad (3)$$

The above two formulas can be simplified as

$$H_{0^\circ} = -H_{ex} - H_c, \quad (4)$$

FIG. 3. Hysteresis loops of the bilayers constructed from the theoretical results of the model.

FIG. 4. Hysteresis loop of the NiFe(100 Å)/NiO(400 Å) bilayer where NiFe was deposited on NiO at RT: (a) H is parallel to easy axis; (b) H is perpendicular to easy axis.

$$H_{180^\circ} = H_{ex} - H_c, \quad (5)$$

where, $H_{ex} = 2(AK)^{1/2}/Mt$ is exchange coupling field; $H_c = |(H_{0^\circ} + H_{180^\circ})/2| = 2(K_I + K_u t)/Mt = 2K_I/Mt + H_k$ is coercivity. Here $H_k = 2k_u/M$ is the anisotropy field of the ferromagnetic layer. In this model, if we apply the field along hard axis, the model predicts that the coercivity $H_c = 0$, and the saturation field H_s , which is equal to the anisotropy field H_k , is equal to H_{0° : $H_s = H_k = H_{0^\circ}$. Thus, theoretical hysteresis loops of the bilayers can be constructed as shown in Fig. 3.

To test this model, NiFe(100 Å)/NiO(400 Å) bilayers were deposited on Si(100) substrates by rf sputtering and the magnetic properties of NiFe/NiO bilayers have been measured by vibrating sample magnetometer (VSM). The experimental data is in good agreement with modeling results. Either Fig. 4 or 5 shows that the anisotropy field H_k determined for hard axis hysteresis loop is approximately equal to the H_{0° . Table II is the magnetic data extricated from hysteresis loops of Figs. 4 and 5. As we can see, the H_k is almost equal to H_{0° , with an error less than 2%. Therefore, experimental data is consistent with model results, and

FIG. 5. Hysteresis loop of the NiFe(100 Å)/NiO(400 Å) bilayer where NiFe was deposited on NiO at a substrate temperature of 300 °C: (a) H is parallel to easy axis; (b) H is perpendicular to easy axis.

TABLE II. The data extricated from Figs. 4 and 5.

Sample	$ H_{\theta=0^\circ} $	$ H_{\theta=180^\circ} $	H_c	H_{ex}	H_k
Sample 1	63.7 Oe	30.8 Oe	16.5 Oe	47.3 Oe	65.0 Oe
Sample 2	78.3 Oe	0	39.2 Oe	39.2 Oe	78.5 Oe

thus also confirms our assumption that magnetization reversal of NiFe/NiO bilayers occurs through rotation. This is consistent with torque measurement conducted by Chih-Huang Lai⁷ which suggests that the magnetization process in the NiFe coupled to NiO is a pure rotation process. Since exchange coupling field H_{ex} is proportional to $2(AK)^{1/2}$, the induced domain wall formed in NiO layer by rotating its interfacial spins plays the decisive role in determining exchange coupling field, H_{ex} , of bilayers. It is reasonable, the wall thickness must be smaller than NiO layer thickness for the bilayer to have exchange coupling field H_{ex} . If the induced domain wall thickness is larger than NiO layer thickness, the spins of the NiO layer rotate irreversibly, causing an increase of H_c . Nevertheless, it cannot contribute exchange coupling field, H_{ex} . Obviously, only the induced domain wall thickness is smaller than NiO layer thickness, can the induced domain wall anchor, and couple to the bulk of the NiO layer, and play the role in determining H_{ex} . It is reported that the NiO layer thickness for NiFe/NiO bilayer having exchange coupling field is around 175 Å.⁷ In our model, the exchange coupling field H_{ex} is predicted to be $2(AK)^{1/2}/Mt$, depending on domain wall energy in the anti-ferromagnet and the thickness of ferromagnet. H_{ex} is predicted to decrease with an increase of the thickness of the ferromagnet, which is consistent with experimental results.⁸ Furthermore, since we have introduced uniaxial interfacial anisotropy K_I into the model, this model predicts that coercivity H_c is $2K_I/Mt + H_k$, decreasing with an increase of thickness of NiFe layer, which has also been confirmed by experiments.⁸ Also this model predicts the smallest H_c we can achieve is uniaxial anisotropy (H_k) of FM layer, which is around 4 to 5 Oe for NiFe films.

Direct observation of the magnetization reversal of epitaxial NiO/NiFe bilayers grown on (001) MgO and on polycrystalline Si substrates was performed by using the magneto-optical indicator film technique. It was shown that the unidirectional-axis magnetization reversal proceeds by domain nucleation and growth. A new phenomenon, an asymmetry in the activity of the domain nucleation centers, has been revealed. Remagnetization of the bilayer is shown to be governed by defect structures in the *antiferromagnetic* layer. © 1998 American Institute of Physics.
[S0021-8979(98)30311-4]

Since the discovery of unidirectional anisotropy¹ numerous investigations of this phenomenon have been carried out in ferromagnetic (FM) thin films deposited onto antiferromagnetic (AF) material.²⁻⁹ The simplest model, proposed by the authors who discovered this phenomenon, incorporates an exchange coupling across the flat interface between FM and AF spins. Because this model fails to describe the magnitude of the measured exchange anisotropy field, H_E , new models have been proposed, involving either planar¹⁰ or vertical¹¹ domain walls in the AF layer. At present, it is established that the exchange shift of the hysteresis loop of a thin exchange-biased FM film depends upon the behavior of ordered spins in the AF. However, the picture is still not entirely clear.

In particular, it is known that the magnitude of the coercive force, H_C , of AF/FM bilayers is much greater than the coercivity of corresponding "free" FM film.^{1,8,12} However, there is no model describing mechanisms responsible for this phenomenon. It is clear that the enhanced coercivity cannot be understood in terms of a spin coherent rotation model.¹ In this case the exchange anisotropy field, H_E , leads only to a shift in a hysteresis loop. The coercivity of the bilayer remains equal to the coercivity of the free FM layer. A model,¹⁰ taking into account the planar domain-wall formation in the AF, leads to the same value of H_C for both small and large interfacial exchange couplings, and even to lowered H_C for intermediate interfacial coupling magnitude.

The magnetization reversal of FM films could proceed by either domain wall nucleation and motion or by nonuniform spin rotation. These processes should have some features when the FM layer is exchange coupled to the AF substrate. These features can be revealed by direct visualization of the magnetization reversal.

In this paper, we study the magnetization reversal of epitaxial NiO/NiFe bilayers grown on both single crystal (001) MgO and polycrystalline Si substrates. In addition, the behavior of exchange-biased NiO/NiFe bilayers is compared with the reversal properties of unbiased NiFe films grown without an AF buffer.

In order to study the magnetization process in epitaxial NiO/NiFe bilayers we use the magneto-optical indicator film (MOIF) technique.¹³ The MOIF technique is based on the Faraday rotation of linearly polarized light in an indicator film, a Bi-substituted iron garnet film with in-plane anisotropy, which is placed on the sample. The polarized light passes through the indicator film and is reflected back by an Al underlayer covering the bottom surface of the film, which is adjacent to the sample surface. While the light is passing through the indicator film its polarization experiences a Faraday rotation through an angle proportional to the component of the local magnetic field parallel to the light propagation direction. The transmitted intensity of the reflected beam through an analyzing polarizer varies with the local field in the light path. The bright or dark variations of the image represent the variations of the perpendicular stray field component. The resulting real time Faraday portrait of the sample's stray magnetic fields presents the information about the static or dynamical domain structure as well as the defects of crystal structure which affect the spin distribution in the sample. The macroscopic hysteresis loops of the films were measured with a vibrating sample magnetometer. In addition, optical reflecting microscopy and a photoelasticity method¹⁴ were used to reveal defects in the thin films.

The NiO(500 Å)/NiFe(100 Å) bilayers were grown in a deposition system using ion beam sputtering onto the single crystal (001) MgO and polycrystalline Si substrates.¹² NiFe(500 Å) films grown onto (001) MgO or onto Si without NiO buffers were also prepared. Both uniaxial (in NiFe) and unidirectional (in NiO/NiFe) anisotropy were established during deposition by means of permanent magnets which produced a 300 Oe uniform bias field in the plane of the substrate.

FIG. 1. Hysteresis loop (a) and MOIF images of domain structure (b)–(h) taken during magnetization reversal of a single-crystal NiO/NiFe bilayer along the $[110]$ unidirectional axis (b)–(e) and in the opposite direction (f)–(h). (b)–(h) are domain structures in the same exact area of the sample and correspond to the conditions indicated by the circles labeled by the same letters on the hysteresis loop in (a). Arrows indicate magnetization directions in domains.

The hysteresis loop and MOIF images of domain structure observed during the magnetization reversal of the NiO/NiFe bilayer grown on the (001) MgO substrate are shown in Fig. 1. The magnetic field was applied along the $[110]$ direction or along the reversed one. The $[110]$ direction coincides with the direction of a magnetic field applied during the bilayer growth. Letters on the hysteresis loop refer to the conditions of the corresponding MOIF patterns. The hysteresis loop exhibits an exchange shift ($H_E = 35$ Oe) and substantial coercivity ($H_C = 40$ Oe). The MOIF patterns display the magnetization reversal of the bilayer proceeds by nucleation and subsequent growth of domains with new magnetization orientations. Moreover, when the magnetic field is aligned along the unidirectional anisotropy axis, the nucleation of domains occurs in central regions of the field of view at some defects [Fig. 1(b)]. However, when the field is aligned in the opposite direction, the domain nucleation starts at other centers [Fig. 1(f)]. Former centers play no role in the nucleation and, moreover, the reversal is finished in their vicinity [Fig. 1(h)]. Thus, we demonstrate the existence of a new phenomenon, a field asymmetry in the activity of the domain nucleation centers.

In the above particular case we do not know what kind of defects play a role as domain nucleation centers. Therefore, we studied crystals of the NiFe and of the NiO/NiFe

FIG. 2. (a), (b) MOIF images of domain structure in a deformed unbiased epitaxial NiFe(001) film created during remagnetization along the $[110]$ easy axis. H (applied field) = -2 Oe and $+2$ Oe in (a) and (b), respectively. Arrows indicate the magnetization directions in domains parallel and antiparallel to the applied field. (c), (d) Domain structure in the deformed part of the epitaxial NiO/NiFe(001) bilayer during the $[110]$ unidirectional-axis remagnetization (corresponds to the right-hand branch of the hysteresis loop in Fig. 1(a)). The arrow indicates the direction of the unidirectional axis and of the applied field. $H = +24$ Oe (c) and $+28$ Oe (d). (e) Surface steps associated with screw dislocation slip planes revealed in a reflected light at the NiFe surface in the NiO/NiFe bilayer. (f) Microstress fields caused by the slip planes of the edge dislocations revealed by a photoelasticity method (Ref. 14). All images are of the same magnification.

bilayers containing dislocations (Fig. 2). These films were grown onto the MgO substrates plastically deformed during cleaving into small pieces prior to the deposition. Figure 2(e) shows NiFe surface steps associated with the intersection of screw dislocation slip planes with the sample surface, are revealed in reflected light on the NiFe/NiO bilayer. Figure 2(f) shows contrast from microstresses surrounding edge dislocations in the same bilayer, as revealed by a photoelasticity method.¹⁴

The easy-axis hysteresis loop of free NiFe layer (grown on MgO without a NiO buffer) demonstrated no shift, and its coercive force was very small (~ 2 Oe). We did not observe any dislocation influence on the domain nucleation in these free NiFe films. This is due to almost zero permalloy magnetostrictive constants. There was also no field asymmetry in the domain nucleation. Domains nucleate and disappear at film edges for both field directions parallel to the easy axis due to the edge stray field. The magnetization reversal proceeds by means of motion of almost rectilinear domain walls

FIG. 3. Hysteresis loop (a) and MOIF patterns showing the domain structure (b)–(d) of the NiO/NiFe bilayer when it is remagnetized perpendicular to the $[110]$ unidirectional axis. The applied field direction is indicated by the arrow. All images are of the same exact sample area.

over the whole sample [Figs. 2(a) and 2(b)]. Though these particular patterns were obtained for the 500 Å thickness sample, such a behavior is typical for free FM films with different thicknesses.¹⁵

In contrast, a surprisingly strong influence of dislocations on the spin rotation and on the domain nucleation was revealed in NiO/NiFe bilayers [Figs. 2(c) and 2(d)]. It is important to note that domains nucleate not only around screw dislocation slip planes (which could create the NiFe magnetization frustrations at the NiO/NiFe interface steps), but also around edge dislocation slip planes. Actually, edge dislocations do not form steps on the interface boundary; their effect is only due to internal stress fields around the dislocation. These stress fields only affect the spin orientation in the antiferromagnet since the permalloy magnetostriction is extremely small.

A very important conclusion can be made from the analysis of the above data. Dislocations in the NiO/NiFe bilayer influence primarily the spin configuration of the AF layer. The spin behavior in the FM layer is affected only through its interaction with the AF layer.

Domain structures observed during the $[1\bar{1}0]$ hard-axis magnetization reversal of the plastically deformed NiO/NiFe bilayer are shown in Fig. 3. The hysteresis loop [Fig. 3(a)] has a symmetric shape and demonstrates a very small coercivity. In this case the magnetization reversal proceeds primarily by the incoherent rotation of magnetization vectors. However, an unusual nucleation of domains has also been revealed in the vicinity of dislocation slip lines. Figures 3(c) and 3(d) demonstrate how elongated domains arise along screw and edge dislocation slip planes.

For comparison, Fig. 4 shows typical domain structures for a polycrystalline NiO/NiFe bilayer (a) and for a polycrystalline free NiFe film (b) grown on Si. The magnetic field was applied along the unidirectional and along the easy axis,

FIG. 4. Domain structure in a polycrystalline NiO/NiFe bilayer (a) and in a NiFe film (b) grown on Si. Both images are of the same magnification ($\times 45$). The magnetic field is applied along the unidirectional and easy axes, respectively. These directions are also, respectively, parallel to the vertical frame of the MOIF pattern.

respectively. Similar to the above results, imperfections in the NiO crucially affect the domain structure of the bilayer. As a result, the bilayer displays a complicated fine-scaled domain structure [Fig. 4(a)]. In contrast, in the polycrystalline NiFe film grown on Si without NiO buffer, the domain structure is simpler and the remagnetization proceeds by the motion of almost rectilinear domain walls with cross ties over large distances [Fig. 4(b)].

In conclusion, we have shown that the domain nucleation and propagation process is responsible for the magnetization reversal in thin-film NiO/NiFe bilayers. This implies that the model of the bilayer hysteresis behavior proposed in Ref. 2 should be extended by consideration of *two-dimensional* inhomogeneities in the AF spin distribution. Preliminary analysis shows that both exchange biasing and enhanced coercivity of the AF/FM bilayer as compared to a free FM layer can be explained in terms of the extended model in a unique manner. Calculations supporting the above suggested mechanism will be published elsewhere.

A spin-polarized scanning tunneling microscope (STM) using a GaAs tip has been studied to observe the magnetization with nanoscale resolution for a sample magnetized in the plane of the film. A STM image of Si(111) 7×7 surface reconstruction using the GaAs tip was observed clearly under ultra-high-vacuum conditions. We found that the cleaved GaAs tip has a capability of high atomic resolution. Next, circularly polarized light irradiated the GaAs tip, and the I - V characteristics were measured for magnetic $\text{Ni}_{80}\text{Fe}_{20}$ and nonmagnetic Au samples. Changes in the tunneling current, which is estimated to be approximately 7%, were observed only for the NiFe sample under the circularly polarized light irradiation. It suggests that the change in the tunneling current is due to the spin-polarized tunneling from the GaAs tip to the NiFe. © 1998 American Institute of Physics. [S0021-8979(98)47711-9]

I. INTRODUCTION

Magnetic recording densities are rapidly increasing. A technique for observing the actual magnetization is required to establish a higher density magnetic recording technique. A spin-polarized scanning tunneling microscope (SP-STM) offers the capability of measuring magnetization at the atomic scale, and has already been studied by some groups.¹⁻⁴ However, these previous studies used magnetic material tips, which might change the magnetization of the sample. We considered GaAs to be suitable for the tip of the SP-STM because of the polarized electron source by circularly polarized light⁵ and the nonmagnetic material. Recently, Prins *et al.*⁶ detected a spin-polarized tunneling current by using a GaAs tip and vertically magnetized Co film. They irradiated laser light to the GaAs tip through a thin Co film. This experimental system is suited for measuring vertically magnetized films. However, the sample condition is very severe, as it should be a thin, vertically magnetized film. We propose a SP-STM using a GaAs tip to observe the in-plane magnetized film. In our experimental system, the laser radiation irradiating the GaAs tip is transmitted parallel to the sample film surface. In this paper, we reported on our observation of STM images using the GaAs tip and we attempted to detect spin-polarized tunneling by measuring the I - V characteristics of the GaAs tip and the $\text{Ni}_{80}\text{Fe}_{20}$.

II. EXPERIMENT

An UHV-STM (JEOL:4500XT) system was used in our experiments. Figure 1 shows our experimental setup. An ul-

trahigh vacuum below the 10^{-8} Pa range was maintained inside the STM chamber. We used a semiconductor laser with a wavelength of 831 nm. Circularly polarized light was produced by combining this laser, a Pockels cell, and a $\lambda/4$ plate. The laser radiation was vertically irradiated to the tip through the viewing port. The laser power before passing through the viewing port was 16 mW. Since the semiconductor laser was invisible, we used a HeNe laser to accurately adjust the optical pass to the sample in parallel. In our UHV-STM system, the sample is biased positively with respect to the tip.

The GaAs tip was fabricated from a (100)-type oriented wafer doped with Zn ($7 \times 10^{17} \text{ cm}^{-3}$) by cleavage in air. Figure 2 shows scanning electron microscope (SEM) images

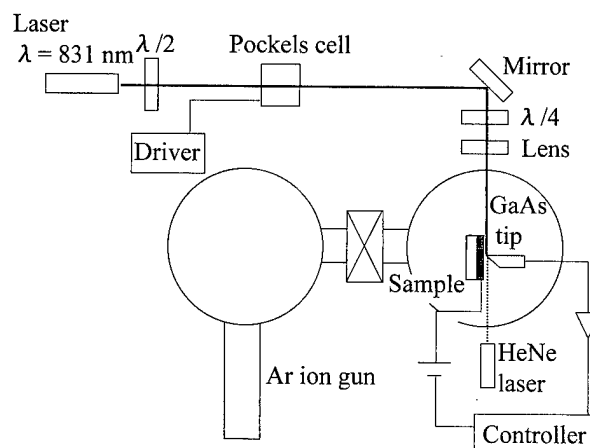

FIG. 1. Experimental setup.

^{a)}Electronic mail: hkodama@flab.fujitsu.co.jp

FIG. 2. (a) SEM image of GaAs tip. (b) Enlarged image.

of the GaAs tip. The wafer corner delimited by the (100), (011), and (110) planes was used as the tip. Circularly polarized light was vertically irradiated to the (100) plane. Figure 2(b) shows an expanded SEM image of the GaAs tip. After being cleaved, the tip was transferred to an UHV-STM chamber and the chamber was heated at 200 °C for 50 h.

A magnetic sample of a thin NiFe film (1000 Å) and a nonmagnetic sample of Au (300 Å) were deposited on a silicon substrate by ion-beam sputtering, which was not *in situ* with the STM. The samples were transferred into an UHV-STM chamber and cleaned by argon ion bombardment of 2 keV and 0.8 μA for 10 min in vacuum below 3.0×10^{-6} Pa. The STM observation showed that the NiFe film has grains about 30 nm wide and has 6 nm of corrugation. The sample magnetization was measured by using a vibrating sample magnetometer, and the coercivity H_C was 1 Oe.

III. RESULTS AND DISCUSSION

Figure 3 shows an image of the Si(111) 7×7 surface reconstruction observed with the GaAs tip. The sample bias voltage was 1.0 V and tunneling current was 0.1 nA.

FIG. 3. Image of Si(111) 7×7 surface reconstruction observed using the GaAs tip. Sample bias voltage was 1.0 V and tunneling current was 0.1 nA.FIG. 4. I - V curves obtained with GaAs tip on Au thin film under irradiation by circularly polarized light. Set point current was -0.5 nA at -0.5 V for all curves.

voltage was 1.0 V and the tunneling current was 0.1 nA. The structure of the Si(111) 7×7 was clearly observed. We found that the cleaved GaAs tip has the capability of high atomic resolution.

First of all, we were concerned with the thermal expansion and the distance change of the sample to the tip when switching on the circular polarization light. We tried to estimate the effects of thermal expansion and distance changes by using Au as the sample. Figure 4 shows the I - V curves obtained with a GaAs tip on thin Au film under circularly polarized light irradiation. The I - V curves were measured continuously for five times, while irradiating with the left-hand circularly polarized light. After switching to the right hand, the circularly polarized light and the I - V curves were again measured continuously for five times. Switching back to the left-hand circularly polarized light, the I - V curves were once again measured continuously for five times. The set point current and voltage were at -0.5 nA and -0.5 V

FIG. 5. I - V curves obtained with GaAs tip on NiFe thin film under irradiation by circularly polarized light. Set point current was -0.5 nA at -0.5 V for all curves. The pumping configuration is shown in the inset. The curve of the upper side was irradiation by right-hand circularly polarized light. The curve of the lower side was irradiation by left-hand circularly polarized light.

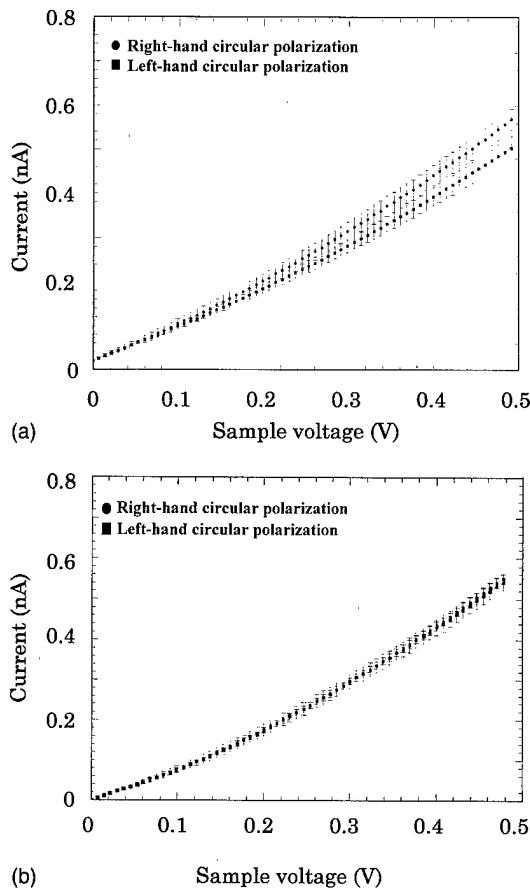

FIG. 6. Positive bias voltage area of I - V curve of the GaAs tip, NiFe sample, and the GaAs tip, Au sample. (a) NiFe-GaAs tip. (b) Au-GaAs tip.

for all curves. The results show that the effects of thermal expansion and distance changes in our system are very small.

Figure 5 shows the I - V curves obtained with a GaAs tip on thin NiFe film while irradiated with circularly polarized light. The procedure for this measurement was the same as in the Au measurement. In Fig. 5, the upper curve represents the case when irradiated by the right-hand circularly polarized light. The lower curve represents the case when irradiated by the left-hand circularly polarized light. Figure 6 shows the expansion chart of the positive bias area of Fig. 4 for the GaAs tip-Au sample, and Fig. 5 for the GaAs tip-NiFe sample. It clearly shows that a tunneling current change was observed only in the NiFe sample. The change in tunneling current at only the positive bias voltage area suggests the occurrence of spin-polarized tunneling, because the tunneling current was only observed with the NiFe sample.

We tried to estimate the current variation P_c from Fig. 6(a), as

$$P_c = \frac{I_R - I_L}{I_R + I_L}. \quad (1)$$

P_c was estimated to be about 7% from Eq. (1). Here, I_L is the tunneling current for the left-hand circularly polarized light irradiation, and I_R is the tunneling current for the right-hand circularly polarized light irradiation. The theoretical polarization of GaAs (P_{GaAs}) is 50%.⁵ The spin polarization of NiFe (P_{NiFe}) is about 30%.⁷ This value is measured by the spin-polarized tunneling technique using a thin-film Al-Al₂O₃-ferromagnetic-alloy tunnel junction. When this value is assumed, the theoretical maximum of variations in the current ratio ($P_{c \text{ max}}$) is defined as

$$P_{c \text{ max}} = P_{\text{GaAs}} \times P_{\text{NiFe}} = 0.5 \times 0.3 = 0.15, \quad (2)$$

and is about 15%. The P_c values in our experiment were about half the theoretical value. We consider that the variation current ratio of 7% is good for an initial attempt, because 15% is the ideal case. The difference between 15% and 7% shows the issue of the surface of GaAs and the spin-relaxation time of the carrier. Furthermore, we tried to increase the P_c value up to 15% using surface treatments and other techniques.

IV. CONCLUSION

This paper reports on observations of UHV-STM images using a GaAs tip. The structure of Si(111) 7×7 was clearly observed. We found that the cleaved GaAs tip has the capability of high atomic resolution. We proposed a SP-STM system that is suitable for observing in-plane magnetized film. An experimental system was developed in which the laser radiation for irradiating the GaAs tip is transmitted parallel to the film surface. Circularly polarized light irradiated the GaAs tip, and we measured the I - V characteristics of magnetic NiFe samples and of nonmagnetic Au samples. As a result, changes in the tunneling current were observed only when the sample was the magnetic NiFe material. This phenomenon suggests that spin-polarized tunneling was observed because the tunneling current change occurred only with the magnetic NiFe sample.

Near field magneto-optical images of magnetic domains in ferromagnetic soft garnet films have been obtained with a scanning tunneling optical microscope working in total reflection geometry with shear-force control of the tip-to-sample distance. In this geometry a magneto-optical contrast is observed for the first time between domains of opposite magnetization without using modulation techniques. When applying a static or alternating external magnetic field, the magneto-optical images provide the location of domain wall pinning points. © 1998 American Institute of Physics. [S0021-8979(98)28511-2]

I. INTRODUCTION

Near-field optics promises to be a powerful technique for magnetic domain imaging with submicronic resolution. Nevertheless, only few experiments have demonstrated such capabilities¹⁻³ and in the total internal reflection geometry [the so-called scanning tunneling optical microscopy (STOM) configuration]⁴ domain visualization has been obtained only by indirect magneto-optical (MO) observation of domain wall motion in a soft ferromagnet.⁵

In the present article, we show that, thanks to the polarization properties of the optical fiber tips that we prepare (Sec. II), near-field MO contrast between domains of opposite magnetization may be obtained in the STOM configuration without using modulation techniques (Sec. III). The MO images presented here provide evidence for domain wall pinning by application of either static (Sec. III) or alternating (Sec. IV) external magnetic fields.

II. EXPERIMENTAL SETUP

A schematic view of the STOM setup that was constructed is drawn in Fig. 1. The sample is deposited on the external face of a semicylindrical prism illuminated by linearly *s*-polarized light (wavelength $\lambda = 647$ nm) at an incident angle beyond the limit of total internal reflection. The evanescent light is collected close to the sample surface by the tip of a tapered monomode optical fiber and guided to a photomultiplier tube (PMT) equipped with a polarization analyzer. The fiber is attached to a dither piezoelectric tube used for shear-force tip-to-sample separation control. The dither tube is in turn attached to a five-electrode piezo tube which allows fine *x*, *y*, and *z* motions of the tip while larger-scale motion of the microscope head is provided by a micrometric mechanical stage. A small coil surrounding the tip is used to apply an external magnetic field perpendicular to the film plane (i.e., parallel to the easy-magnetization axis of the sample) to change the magnetic structure of the sample.

The tip-to-sample separation is regulated by a novel shear-force detection technique. An ac voltage is applied to the dither piezo tube at a resonant vibration frequency of the fiber. The impedance variation of the piezo tube at this frequency is measured with a Wheatstone-type bridge via a lock-in amplifier. When the tip approaches the surface, the oscillation amplitude of the fiber decreases due to shear-force interactions and an impedance change of the piezo oscillator is detected. The related variation of the lock-in amplifier output signal is used in a feedback loop to control the tip-to-sample distance. This provides the topography of the surface independently and concurrently to the optical image, which is essential for the interpretation of the near-field optical contrast. Our shear-force measurement is comparable with several other electrical detection techniques recently proposed⁶⁻⁹ and provides many advantages when compared to standard optical detection techniques.^{10,11} It is easy and fast to set up as no tedious optics alignment is required. Scanning the tip over the surface does not change the measurement. The signal-to-noise ratio is high (better than 1000 in a 25 Hz bandwidth). The free space available around the tip is used to set the magnetic coil.

FIG. 1. Schematics of the scanning optical microscope setup.

^{a)}Electronic mail: pb@pmc.polytechnique.fr

Since the measurement of small MO effects requires a high degree of polarization sensitivity and a high collection efficiency, which both crucially depend on the tip condition, we have developed a fiber-pulling apparatus with a novel soft multiple-step procedure which strongly contrasts with the commonly used two-step fabrication process.¹² A weak pulling force is applied to the fiber during the whole process. A step-by-step taper of the fiber is provided by pulsed operation of a CO₂ laser (Synrad E-48-1) power stabilized by a homemade additional supply of the rf drive. The small elongation produced by each pulse is measured. This value is used to define the time width of the following laser shot. Between two subsequent pulses a time delay is provided to cool down the fiber. After about one hundred of these pulse-and-cool-down sequences, the diameter of the fiber taper neck is reduced (by about 1 μm steps) from 125 to nearly 8 μm . For the final tip formation a last laser shot is applied with only the weak pulling force previously mentioned and switched off when a specified fiber drawing speed is reached. This procedure permits control of the tip geometry and is used to create single-cone-shape tips with typical angles of 25°. This provides good mechanical properties for shear-force measurements and high light-collection efficiency. Shear-force and optical lateral resolutions better than 50 nm are achieved with these tips. From near-field optical measurements performed on a bare prism with polarized light, the tips exhibit characteristic collection properties of a dipolelike near-field probe.⁵ Collection efficiency in the surface plane is isotropic and extinction ratios as high as 1000:1 are reproducibly achieved for both *s*- and *p*-polarized light.

III. NEAR-FIELD MO IMAGING OF DOMAINS

The sample that we have studied is a 1- μm -thick single-crystal ferromagnetic garnet film grown on a garnet (GGG) substrate. Its magnetic properties are well known.¹³ This garnet is a soft ferromagnet with a saturation magnetic field H_s of a few Oe. The magnetic domain size is on the order of 4 μm and the easy-magnetization direction is perpendicular to the film plane. We denote φ as the angle between the analyzer and the incident light polarization. In the small Faraday rotation limit ($\tan(\theta_F) \approx \theta_F$) and assuming zero ellipticity, the intensity $I(\varphi)$ collected above the surface in near field is

$$I(\varphi) = I(0)[\cos^2(\varphi) + \theta_F^2 \sin^2(\varphi) + \theta_F \sin(2\varphi)]. \quad (1)$$

The sign of θ_F changes with the sign of the magnetization leading to a MO contrast between two domains of opposite magnetizations equal to $\Delta I(\varphi) = 2\theta_F \sin(2\varphi)I(0)$.

Figure 2(a) represents the shear-force topographic image of a 17 $\mu\text{m} \times 17 \mu\text{m}$ area of the sample surface. The surface roughness is a fraction of nanometer and the topographic image does not show any particular structure except a small defect of 400 nm lateral size and 10 nm height. Figure 2(b) shows the near-field MO image of the same area as Fig. 2(a), recorded simultaneously, and corresponding to $I(\varphi)$ for $\varphi \approx 85^\circ$. There is no external magnetic field and the scanning frequency is 4 Hz. A strong contrast between domains of opposite magnetizations is observed, which we checked to be reversible by inverting the polarization-analysis angle φ .

Figure 3(b) shows a 2.4 $\mu\text{m} \times 2.4 \mu\text{m}$ MO image re-

FIG. 2. Image (a) is a 17 $\mu\text{m} \times 17 \mu\text{m}$ shear-force topographic image of a garnet film surface. The other images are near-field MO images of the same sample area measured with a constant external magnetic field equal successively to (b) 0%, (c) 39%, (d) 47%, and (e) 55% of H_s . The last near-field MO image (f) is taken when the external magnetic field is reset to zero.

corded in the vicinity of a domain wall. The curve plotted in Fig. 3(a) corresponds to the profile of $I(\varphi)/I(0)$ along the horizontal line in Fig. 3(b) indicated by the arrow. As can be seen, the full grey scale of the image represents a few tenth of a percent of $I(0)$. The MO contrast of 2×10^{-3} , with a signal-to-noise ratio larger than 5, corresponds to a Faraday rotation $\theta_F \approx 0.3^\circ$. The apparent width of the domain wall is 0.3 μm . This value is somewhat larger than the ones usually quoted.¹³ This is possibly due to the thickness of our sample ($\approx 2 \mu\text{m}$). Finally, the domain wall shape does not appear to be uniform at the submicron scale.

When an external constant magnetic field is applied, the relative size and morphology of the magnetic domains change by motion of the domain walls. The size of the domains with magnetization parallel to the field (bright areas) increases while the size of the domains with opposite magnetization (dark areas) is reduced. This is illustrated in Figs. 2(c)–2(e) which have been obtained in external magnetic fields equal to 39%, 47%, and 55% of H_s , respectively. Two regimes are clearly identified during this process. The first occurs between Figs. 2(b) and 2(c), where magnetization reversal mainly changes the width of the domains without modifying the general domain configuration. The second regime is observed between Figs. 2(c) and 2(e). After the domain width has reached a minimum critical value measured

FIG. 3. The left-hand view is the profile of the near-field optical signal $I(\varphi)/I(0)$ corresponding to the line indicated by the black arrow of the 2.4 $\mu\text{m} \times 2.4 \mu\text{m}$ right-hand near-field MO image. Submicron structures along the domain wall are observed.

FIG. 4. The images (a) and (b) are obtained simultaneously on a $14\text{ }\mu\text{m}\times 14\text{ }\mu\text{m}$ area of the garnet film. They are recorded (a) without and (b) with an alternative external magnetic field. The contrasted lines in view (b) are related to the domain wall motion induced by the magnetic field modulation.

to be $1.3\text{ }\mu\text{m}$, the reversal of magnetization is mainly governed by domain shortening and/or collapse. The end of the black stripe domains appears in the image area before one domain is swept out of the scanned area.

Moreover one clearly sees that the defect observed in Fig. 2(a) pins a domain wall. Indeed, except in Fig. 2(e), i.e., close to the saturation of the sample magnetization, a domain wall is always near the defect. Images, not presented here, have been recorded at intermediate field values between those of Figs. 2(c) and 2(e). These additional images show that the end of the right-hand dark stripe domain moves with increasing magnetic field until it reaches the defect. From this stage, when the external magnetic field is increased from 47% to 53% of H_s , the left-hand dark domain termination still moves over $6\text{ }\mu\text{m}$ while the right-hand dark domain termination remains pinned on the defect. The right-hand dark domain jumps then out of the image for a very small additional increase of the magnetic field value from 53% to 57% of H_s . Finally, when the magnetic field is reset to zero as in Fig. 2(f), a new domain wall is again pinned on the same defect, although the domains configuration is different from the one existing before the large field application. This observation is reproducible with multiple magnetization cycles.

IV. NEAR-FIELD MO IMAGING OF DOMAIN WALLS

It has already been shown that applying an alternating magnetic field of amplitude much smaller than H_s causes a domain wall to oscillate around its location in zero external magnetic field.⁵ In the area where this motion takes place, the magnetization is periodically flipped and results in a MO modulation $\Delta I(\varphi)$ of $I(\varphi)$. Elsewhere, inside the domains, the magnetization is not modified and $I(\varphi)$ is constant [$\Delta I(\varphi)=0$]. Displaying $\Delta I(\varphi)$ through lock-in detection, images exhibit contrasted regions which correspond to the wall motion.

Figure 4 presents two images recorded on the same $14\text{ }\mu\text{m}\times 14\text{ }\mu\text{m}$ sample area. On Fig. 4(a), $I(85^\circ)$ is displayed without external magnetic field according to the static procedure described in Sec. III and Fig. 4(b) is obtained from $\Delta I(45^\circ)$ for an alternating field with an amplitude of a few percents of H_s . The magnetic field modulation frequency is

511 Hz. Several modulation frequencies from 80 Hz to 2 kHz have also been used without any change in the images. In both images the contrast of the MO signal can be reversed by changing the sign of φ . As expected, the contrasted areas in Fig. 4(b) coincide with the boundaries between domains of opposite magnetization in Fig. 4(a). However some of the domain walls in Fig. 4(b) exhibit discontinuities where $\Delta I(\varphi)=0$. These contrastless areas correspond to static points of the walls that we interpret as pinning points. It is very important to note that these points cannot be observed either in the zero magnetic field MO image of Fig. 4(a) or in the topographic image of the surface (which is not reproduced here).

V. CONCLUSION

In summary we have demonstrated in Sec. III the possibility to image magnetic domains in the STOM geometry with polarizer and analyzer almost crossed without using any modulation technique. A high MO contrast between domains of opposite magnetizations is obtained with quite large signal-to-noise ratio for Faraday rotations of about 0.3° . Fine features of the domain wall shape are shown. The MO images, obtained by application of static (Sec. III) or alternating (Sec. IV) external magnetic fields, allow to identify two types of domain wall pinning defects, respectively, correlated or uncorrelated with topographic structures. The results presented here are very promising for high resolution MO imaging of ultrathin (a few tens of nm) metallic magnetic multilayer films with similar Faraday rotations. Moreover the oblique incident angle in total reflection geometry should permit near-field MO imaging of domains not only in materials with perpendicular magnetic anisotropy but also with in-plane magnetization.

Induction mapping of magnetostrictive materials

Jennifer Dooley

Jet Propulsion Laboratory, Pasadena, California 91109

Marc De Graef^{a)} and Michael E. McHenry

Department of Materials Science and Engineering, Carnegie Mellon, Pittsburgh, Pennsylvania 15213

An energy-filtered magnetic induction mapping technique has been implemented on a JEOL 4000EX equipped with a Gatan imaging filter. A study of the magnetic domain structure in Terfenol-D, a magnetostrictive actuator material, is presented as an example application of the technique. The method is equivalent to differential phase contrast microscopy by the reciprocity theorem. Image simulations of all stages of the induction mapping process are shown to support these observations. © 1998 American Institute of Physics. [S0021-8979(98)47811-3]

INTRODUCTION

There is a growing interest in both room-temperature and very-low-temperature magnetostrictive actuator materials. Terfenol-D, a rare-earth transition-metal magnet, possesses a room-temperature magnetostrictive strain of about 0.2%, the largest known.² Ni_2MnGa exhibits large magnetostrictive strains, which arise from a magnetically induced martensitic transformation in a temperature range near room temperature.³ Polycrystalline rare-earth low-temperature magnets have recently been shown to retain a significant fraction of the magnetostriction of the single crystals, and are considerably less expensive to produce.⁴ Determination of the fine scale magnetic structure is essential for prediction of, among other things, the bulk magnetostrictive strains. In addition, since virtually all engineering parameters of these materials are directly affected by microstructural features, the nature of these materials makes it necessary to closely combine the study of magnetic structure and microstructure. Lorentz microscopy, in particular, the Fresnel and Foucault observation modes,⁵ has for several decades been the dominant observation technique for qualitative magnetic domain observations.

The decreasing length scale of modern electronic and magnetic devices must be accompanied by improvements in the observation techniques used to study their micro- and nanostructures. The low-field sample environment and consequent increase in the focal length of the objective lens required for Lorentz microscopy results in a reduced final image magnification as compared to that of conventional transmission electron microscopy (TEM). This represents a serious limitation in the quantitative study of nanoscale magnetic structures. Furthermore, inelastic scattering in the sample contributes noise to the images, which further limits the attainable resolution of the standard Lorentz modes.

There are very few techniques capable of producing direct maps of the (in-plane) magnetic induction in a thin foil. Differential phase contrast (DPC) microscopy in a scanning TEM⁷ is perhaps the most successful method, but it requires the installation of descanning coils and a four-quadrant de-

tector, which are not accessible in the average research laboratory. For this method, the descanning coils are aligned such that any tilt of the beam arising from the scanning coils is compensated for at the plane of the quadrant detector so that any remaining shift of the beam over the detector is due to the Lorentz deflection. The magnitude of this deflection is measured as the difference signal from opposite quadrants of the detector and can be directly related to the components of the magnetic induction in two orthogonal directions $\pm U$ and $\pm V$. A technique equivalent to DPC by the reciprocity theorem for the TEM was proposed and implemented by Daykin and Petford-Long.⁸ This induction mapping technique has been adapted to the 4000EX+GIF (Gatan imaging filter) combination, the method has been applied to the Terfenol-D system, and simulation algorithms have been created for the mapping technique.

EXPERIMENTAL METHODS

This article presents a summary of energy-filtered Lorentz observations of the Terfenol-D system. A Lorentz microscopy setup, which combines a high-resolution top-entry JEOL 4000EX TEM with a postcolumn GIF, has been previously reported.⁶ With the main objective lens turned off, the sample is mounted in an essentially field-free region. The objective minilens, which sits below the plane of the specimen, provides sufficient field strength to focus the electrons into a diffraction pattern at the selected area aperture plane, thus providing Fresnel and Foucault observation modes. The energy filter provides an additional magnification of approximately $20\times$, and allows for the acquisition of zero-loss images, increasing the signal-to-noise ratio by at least an order of magnitude.⁶ The magnetic resolution of this system is better than 5 nm.

All images in this paper were obtained from a thin foil of Terfenol-D, or $\text{Tb}_{0.73}\text{Dy}_{0.27}\text{Fe}_{1.95}$, which has a cubic Laves phase structure ($a = 0.732$ nm).⁹ Single-crystal rods of Terfenol-D with $[211]$ growth direction were obtained from Etrema, Inc. These were oriented by reflection Laue diffraction and cut into disks with $[01\bar{1}]$ foil normal. Dimpled disks were then jet thinned in a chilled solution of 10% perchloric/90% acetic acid and ion milled for several hours with 4.5 kV

^{a)}Electronic mail: degraef@cmu.edu

FIG. 1. Foucault image of a representative magnetic domain structure in Terfenol-D. This region is used in the induction maps of Fig. 2.

Ar^+ ions until electron transparent. For a detailed description of the microstructure of this material the reader is referred to Refs. 10, 11, and 6. Figure 1 shows a Foucault image of a characteristic lamellar domain arrangement. This area of the sample is used throughout the paper to illustrate the methods.

Magnetic induction mapping in the TEM was first introduced in Ref. 8 and adapted to the 4000EX+GIF combination in Ref. 6. A converged incident beam, with beam divergence angle θ_c , illuminates the region of interest on the sample. A small aperture truncates the transmitted beam in the back focal plane of the objective minilens and beam tilts are provided through the postspecimen image shift coils. The beam is tilted and images obtained with consecutive tilts are added together (approximating an integral with respect to beam tilt) and constitute the equivalent of the quadrant detector signals in DPC. For full details on the method the reader is referred to Ref. 12.

INDUCTION MAPPING RESULTS

Figure 2(a) shows four series of zero-loss Foucault images (slit width 15 eV), for two orthogonal tilt directions. The reader is referred to Ref. 12 for a description of the calibration of the tilt directions with respect to the microstructure. After aligning the Foucault images in each series they were summed on a per-pixel basis. The sums are shown in Fig. 2(b), along with the difference maps. Since the intensity in the difference map is proportional to the in-plane induction component in one of the two orthogonal directions, the difference maps can be represented as a single vector induction map, as shown in Fig. 2(c).

Using an image simulation algorithm developed by Mansuripur,¹³ a method similar to standard high-resolution simulations has been implemented for the computation of magnetic induction tilt series and difference maps for a given magnetic structure.¹² The results are shown in Fig. 3. The

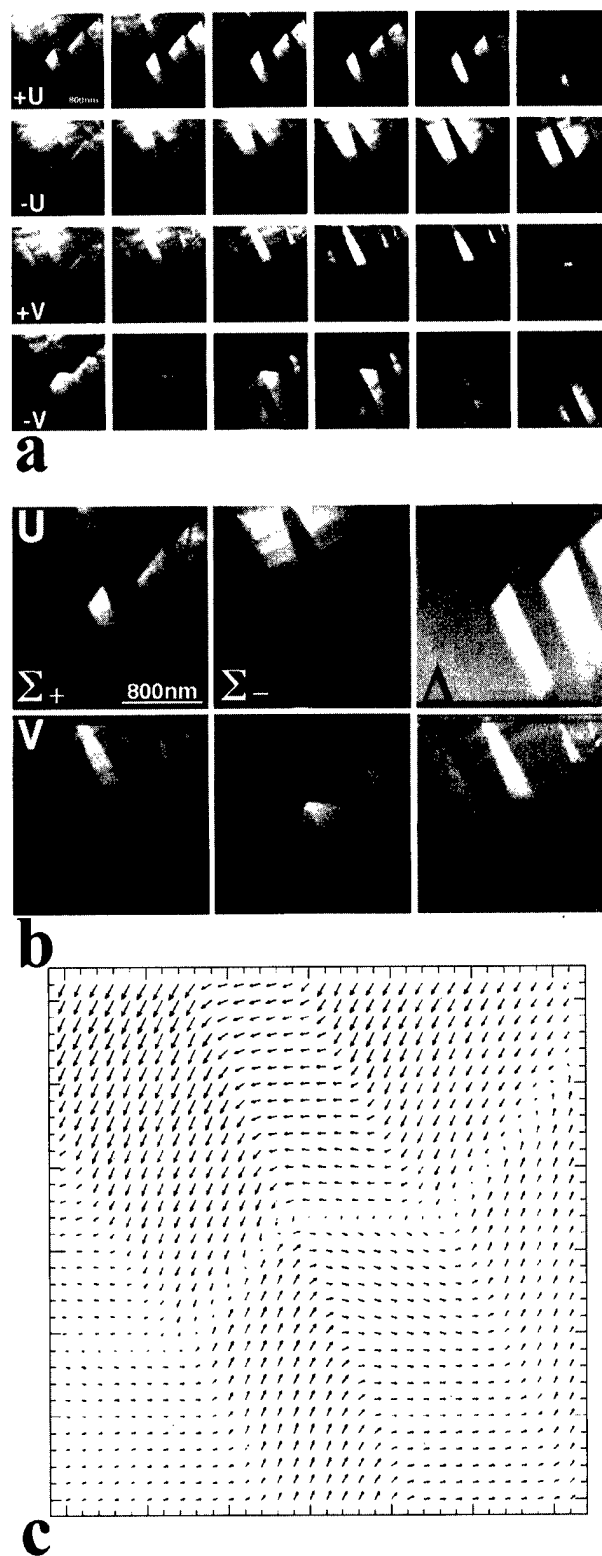

FIG. 2. (a) Foucault images as a function of postspecimen beam tilt for two orthogonal tilt directions. (b) Foucault sums and difference maps. (c) Vector induction map, created from the energy-filtered difference maps.

simulations were carried out for a 16 nm domain-wall width for the 180° Bloch-type wall, 10 nm for the 71° domain walls, a saturation magnetic induction of 1 T, foil thickness of 100 nm, beam divergence angle $\theta_c = 1$ mrad, a beam tilt increment of 3.5 μrad , aperture radius of 0.05 nm^{-1} , and an

FIG. 3. Simulated summed tiltseries corresponding to Fig. 2(b); the top part of the simulated images is to be compared with the 180° domain-wall in Fig. 2(b).

incident beam energy of 400 kV. Tilt directions in the simulation were taken to be the same as in the experiment. The domain-wall profile from the filtered experimentally reconstructed map is shown in Fig. 4(a). The reconstructed 180° domain-wall width is estimated to be 83 nm, as each pixel corresponds to about 4.14 nm. For this case, one tilt direction was close to the normal of the domain wall. Figure 4(b) shows the simulated reconstructed map and the input profile.

Good qualitative agreement exists between these sets of images, including the presence of a faint bright fringe in the experimental $\pm U$ sums. The reconstructed vector map compares favorably with the experimental map in Fig. 2(b), as do the domain-wall profiles.

ACKNOWLEDGMENTS

Simultaneous magnetoresistance measurements and observation of magnetic domain structures have been performed on active spin-valve elements by means of *in situ* experiments in a Lorentz transmission electron microscope. Two different spin-valve structures with NiFe and NiFe/Co sense layers have been studied with two sizes of rectangular elements. The effect of different applied current values has been analyzed and the addition of a Co layer in the sense layer has a large influence on the spin-valve behavior and on the domain structure. Also, two different processes for magnetic domain growth and motion have been observed for low or high applied current densities.

© 1998 American Institute of Physics. [S0021-8979(98)17711-3]

INTRODUCTION

Numerous studies on spin-valves (SVs) have been performed over the past few years motivated by the promising use of SV structures in magnetoresistive storage systems.¹ A very good overview on SV structures and giant magnetoresistance (GMR) has recently been published.² For a better understanding of the micromagnetics of these materials, previous studies have been carried out on ferromagnetic (FM) thin films objects³ and on SV elements.⁴ In this article, we report on *in situ* experiments which enabled us to observe, by means of Lorentz electron microscopy,⁵ the magnetic domain evolution of active SV elements, namely, those through which different currents are being passed. The goal of this study is to analyze the behavior of active SV elements. We report results on the effect of the applied current value, the effect of the additional Co layer, and also that of the element size.

EXPERIMENTAL DETAILS

In situ experiments and observations in the Foucault mode of Lorentz microscopy were carried out using a modified JEOL 4000EX transmission electron microscope (TEM) operated at 400 kV and fitted with an AMG40 low-field objective lens pole piece. The SVs were deposited on a 40 nm alumina membrane by dc magnetron sputtering in a Sputtered Films, Inc. planetary deposition system. A 70 Oe field defined the easy axis during deposition. More details on the device configuration and fabrication are given elsewhere.⁶ The exchange anisotropy is about 500 Oe and the anisotropy field varies between 3 and 10 Oe depending on the sense layer structure and on the current value. Various currents were applied through the SV elements and, by monitoring the change in applied field (H_a), the GMR ratio of the sample could be plotted using $dR/R = (R - R_{\text{sat}})/R_{\text{sat}}$. The R_{sat} value corresponds to the parallel state of the magnetic

moments in the FM layers. The applied field, parallel to the easy axis and to the long axis of the elements, was changed by 1 Oe every 10 s in order to keep constant any time-dependent effects. This configuration has been preferred to the most commonly used one in recording applications (applied field along the hard axis) because the effects induced either by the sense layer structure or by the current density are more visible.

RESULTS AND DISCUSSION

The different configurations investigated are reported in Table I. For each of the samples, we have plotted the GMR curves for current values of 0.3, 2, and 3.5 mA during simultaneous observation of the magnetization reversal. Figure 1 shows the results obtained for samples 1 and 3 ($10 \mu\text{m} \times 30 \mu\text{m}$ elements with NiFe [Fig. 1(a)] and NiFe/Co [Fig. 1 (b)] sense layers). One can notice a shift of the curves with respect to remanence in both cases. This feature is most probably a result of FM coupling between the FM layers, mainly explained by roughness at the interfaces between the magnetic and nonmagnetic layers. According to the data in Table II, higher GMR ratios (in agreement with previous studies⁷), higher FM coupling, and higher coercivity (H_c) of the sense layer are observed for sample 3 than for sample 1 due to the presence of Co in the sense layer. With a higher current through the elements, there is a decrease in the GMR ratios, coercivities, and FM coupling in both cases and the slope of the GMR curves becomes more abrupt (more particularly for

TABLE I. Summary of the different configurations investigated.

Sample	Structure	Thicknesses (nm)	Sizes (μm)
1	NiFe/Cu/Co/NiFe/MnNi	8/3/2/6/25	10×30
2	NiFe/Cu/Co/NiFe/MnNi	8/3/2/6/25	4×10
3	NiFe/Co/Cu/Co/NiFe/MnNi	6/2/3/2/6/25	10×30
4	NiFe/Co/Cu/Co/NiFe/MnNi	6/2/3/2/6/25	4×10

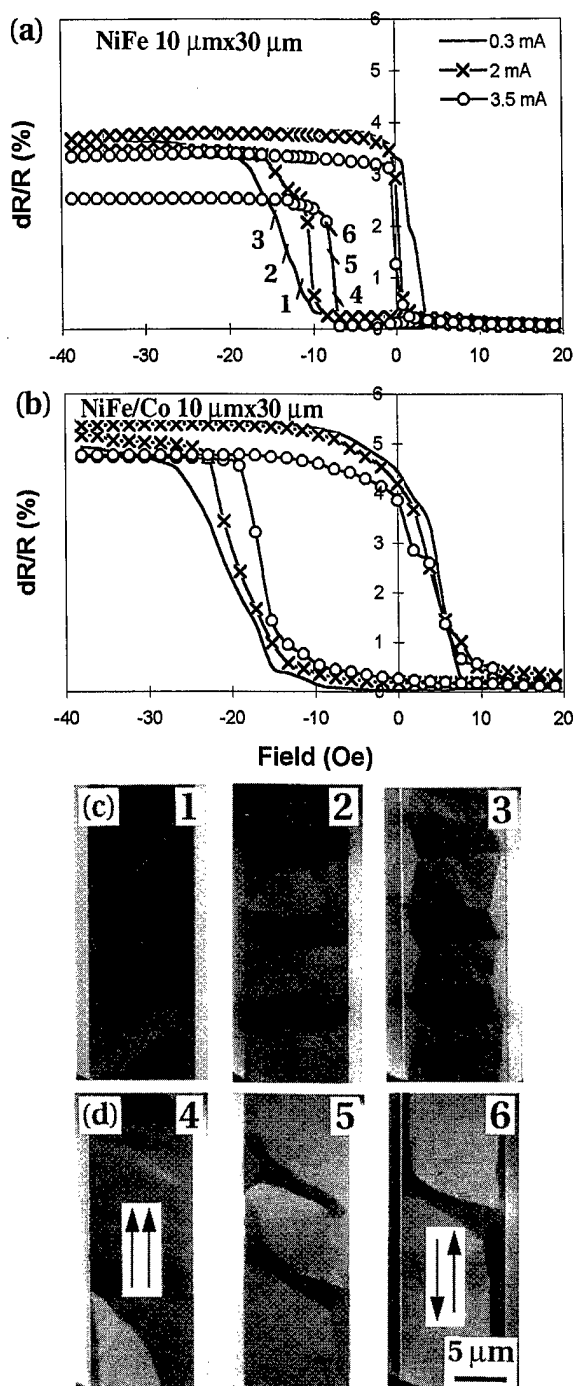

FIG. 1. (a), (b) Plots of GMR curves vs applied field for samples 1 and 3, respectively, and for current values of 0.3, 2, and 3.5 mA. The numbers in (a) refer to the Foucault images in (c) and (d) showing the evolution of the domain structure of sample 1 during the P-AP transition for current values of 0.3 and 3.5 mA, respectively. The applied field is pointing down vertically and the easy axis is in the opposite direction. Contacts are on the tops and bottoms of the images.

sample 1). Figures 1(c) and 1(d) show Foucault images of sample 1, corresponding to the transition from parallel (P) to antiparallel (AP) alignment of the magnetization in the FM layers for applied current values of 0.3 and 3.5 mA, respectively. The contrast shows the domain structure in the sense layer during the reversal assuming that the pinned-layer

magnetization is fixed and is parallel to the long axis of the element. The difference in slope observed in Fig. 1(a) is explained by a quicker reversal mechanism for the higher current values. For a low current, the magnetization direction of the sense layer gradually rotates within the domains (leading to an increase in ripple contrast) as the applied field changes [see images 2 and 3 in Fig. 1(c)]. The domain structure corresponding to the higher current value [see images 5 and 6 in Fig. 1(d)] shows larger domains with no ripple contrast. For sample 1, the limit of current value above which the SV element begins to be damaged by heating effects is around 4 mA. The GMR curve of sample 1 for the current value of 3.5 mA is not closed, meaning that some pinning effects between the two FM layers begin to affect the reversal mechanism. $R(I)$ and $R(T)$ measurements have been performed on sample 1 (not shown). For a current value of 3.5 mA, the resistance value has increased from 48Ω (at room temperature) up to 60Ω which corresponds to the resistance value obtained for a temperature of about 230°C . We therefore believe that the difference in reversal mechanism between Figs. 1(c) and 1(d) is a result of the increase in thermal energy provided by the 3.5 mA current value. For sample 3, the domain configuration (not shown) at 0.3 mA is identical to that of sample 1. At 3.5 mA, its domain structure is similar to that obtained for 0.3 mA but with much less ripple contrast.

Figures 2(a) and 2(b) show the GMR curves recorded for samples 2 and 4 ($4 \mu\text{m} \times 10 \mu\text{m}$ elements with NiFe and NiFe/Co sense layers, respectively) for applied current values of 0.3, 2, and 3.5 mA. Figures 2(c) and 2(d) are Foucault images of sample 2 taken during the P-AP transition for applied current values of 0.3 and 3.5 mA, respectively. The differences between NiFe and NiFe/Co SV properties as well as the evolution of the GMR ratio, coercivity, and FM coupling with the various current values are similar to the previous case. However, one can observe a much higher coercivity (see Table II). Such a result is the consequence of the shape anisotropy which increases as the stripe width is reduced ($H_c = 4\pi Mt/h$ where M is the saturation magnetization, t the thickness of the film, and h the stripe width). Also, the presence of pinning sites explained by corrosion and oxidation from the sides which occur during lithographic process could favor an increase in coercivity.⁸ Otherwise, the domain configurations shown in Figs. 2(c) and 2(d) are very similar to those corresponding to the previous section despite the lower size of the element. This feature allows us to think that the domain structure is more related to the *shape* of the element than to its size.

We want to emphasize that all these results and observations are very reproducible up to the limit of the current values given in Table II. These limits are more than one order of magnitude lower than that used in actual SV recording heads.⁹ The higher limit (4.5 mA) for samples 3 and 4 is consistent with the good thermal stability of Co in metallic multilayers.¹⁰

CONCLUSION

These results confirm clearly that the presence of a thin cobalt layer in the sense film increases the GMR ratio, the

TABLE II. Summary of the magnetic properties.

Sample	H_c sense layer	H_c sense layer	GMR ratio	GMR ratio	Limit ^a of	FM coupling	FM coupling

coercivity, the FM coupling, and the thermal stability of the SV element. A decrease in the element size results in an increase in coercivity, probably due to the shape anisotropy, but it is worth noticing that the domain structure is very similar for the two sizes studied, indicating that the shape of the element is crucial for determining the domain configuration. An increase in the current density decreases the GMR ratio and the coercivity, and induces quicker transitions (lower anisotropy field) and larger domains for the reversal mechanism, these effects being more pronounced for the NiFe sense layer SV. As the contribution of the field induced by the sensing current is quite low for such a range of current values, the differences in domain structures between low and high current densities are mainly due to the increase in thermal energy of the element.

The stray flux manifestations of surface magnetic domains found in as-grown $\text{Nd}_2\text{Fe}_{14}\text{B}$ single crystals were observed, with a resolution in the range of $1\text{ }\mu\text{m}$, using conventional scanning electron microscopy (SEM) without instrumental modifications. A modified image-distortion mode was applied to image the three-dimensional stray flux emanating from the sample. The simplicity of the technique and the ready adaptability of the SEM to such modifications as *in situ* current and magnetic field application suggest that the results of this study may be extended to investigations of other materials of technological interest, such as perpendicular media disks. © 1998 American Institute of Physics. INTRODUCTION

The magnetic domain structure of magnetically ordered materials provides information of both fundamental and applied technological interest. Data concerning the micromagnetic state, the influence of inhomogeneities on the position of domain walls, and direct determinations of the domain size and behavior under dynamical conditions are useful for the determination of materials parameters as well as for the confirmation of modeling predictions. On the more practical side, magnetic domain imaging can be used as a quick way to ascertain the presence, character, and effects of defects in recording media, recording heads, and transformer alloys.

Magnetic domain images may be generated by a variety of techniques, each with its particular strengths and drawbacks.¹ Scanning electron microscopy (SEM) allows magnetic domains of bulk materials to be imaged by the deflection of a beam of incident electrons from the surface of a ferromagnetic material under the influence of $\mathbf{F}_{\text{Lorentz}}$. In this work, the applicability of SEM for imaging magnetic domains is demonstrated on a single-crystal specimen of $\text{Nd}_2\text{Fe}_{14}\text{B}$. It is hoped that a demonstration of the relative ease of this technique, combined with the adaptability of the SEM to such modifications as external field and current application as well as environment and temperature control, may prove to be helpful for researchers in both academia and industry.

EXPERIMENTAL DETAILS

Single crystals with the composition $\text{Nd}_2\text{Fe}_{14}\text{B}$ were grown out of a Nd-rich melt from high-purity elements placed in a tantalum crucible and cooled at $\sim 1\text{ }^\circ\text{C/h}$ from 1190 to 800 $^\circ\text{C}$. After cooling, well-formed prismatic crystals were removed from the excess flux. Room-temperature demagnetization curves indicate that the crystal possesses a coercivity under 1 Oe.

The magnetic domain observation was performed on a JEOL Model 6400 scanning electron microscope using a LaB_6 filament operated at 6 kV and 9 nA. The collector bias voltage was set at the factory to vary with the accelerating voltage, thus producing a high signal-to-noise ratio. The scanning electron microscope has not been modified or augmented in any way. Depending upon the domain characteristics of the material under investigation, either the type I or the type II contrast mode is available in SEM to image magnetic domains.² Type I contrast is applicable when the emitted secondary electrons possess a relatively low kinetic energy ($< 10\text{ eV}$) sensitive to deflection by the stray field emanating from the surface of the magnetic material. Type I contrast is operative on high anisotropy, uniaxial materials with surface stray fields unconfined by closure domains to remain within the material, which are characteristics of $\text{Nd}_2\text{Fe}_{14}\text{B}$. These surface stray fields reside above alternate domain walls and exert Lorentz forces $\mathbf{F}_{\text{Lorentz}}$ on the secondary electrons which are deflected in opposite directions, depending upon the polarity of the stray field. Magnetic contrast is produced when an unequal flux of secondary electrons reach the detector, positioned at an angle to the sample's surface. In this manner the intensity of domain contrast varies from a maximum to a minimum across a single domain.^{3,4} The domain contrast obtained by SEM is highly influenced by the surface morphology, because secondary electrons also give rise to a topographical image. In order to insure that the crystal surfaces were as smooth as possible, the specimen was mounted in a Gatan dual ion mill on a special sample holder to accommodate its thickness. The specimen surfaces were first ultrasonically cleaned in acetone and then ion milled in an Ar^+ beam for a total of 6 h at 3 kV and 0.5 mA. Metallic luster, in addition to a significant increase in the clarity of the domain images, was then obtained after this treatment. Experiments were conducted with the samples in the "as-is" condition except for the surface cleaning procedure described above. The initial working distance of the microscope was set at 39 mm, where it is ex-

FIG. 1. Macroscopic view of the domain configuration on the (001) surface of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ crystal.

pected that the external field from the objective lens would have little effect on the sample.⁵ Optical Kerr microscopy was also performed on same crystal at Rhône-Poulenc Inc. for image comparison.

RESULTS AND DISCUSSION

Figure 1 presents the familiar maze pattern of domains visible on the (001) plane of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ single crystal. No change of the macroscopic domain structure of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ crystal was observed with change in focusing strength, even at the shortest working distance allowed by the system (8 mm). Thus the magnetic field, due to objective lens, experienced by the sample is less than the coercivity of the crystal (1 G). Higher magnifications of the maze pattern reveal a fine structure which appears to consist of strings of neutral-grey beads separated by light and dark undulating lines. Figure 2(a) shows the magnetic domain images formed by electrons influenced by the Lorentz force $+F_{\text{Lorentz}}$. Features on the order of $1\ \mu\text{m}$ may be resolved. Each "bead" in the string is elliptical in shape, with the eccentricity increasing from round on the (100) surface to more elongated on other surfaces. The depth-of-field of the secondary electron imaging process produces a third dimension, causing the strings of beads to appear either concave-up or concave-down in alternate rows. By rotating the sample through an angle of 180° a change in the contrast is produced, because the Lorentz force changes in sign. This phenomenon is shown in Fig. 2(b), where the circled feature which possesses a concave-up appearance in the top portion of Fig. 2(b) possesses a concave-down appearance in the bottom portion of the figure. Kerr microscopy, Fig. 2(c), confirms that imaged "beads" are in reality spike domains, residing in rows of alternating magnetization between the larger stripe or "parallel plate" domains which extend through the bulk of the material. Spike domains are expected to form on the surfaces of uniaxial magnetic crystals with very high anisotropies,

FIG. 2. (a) Higher-magnification image of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ crystal, illustrating the fine structure of the domains. (b) Top: domain structures imaged at a rotation angle of 0° . Bottom: Specimen rotated by 180° relative to the original orientation. Circled regions indicate an inversion of the domain depth of field contrast. (c) Kerr micrograph of the same crystal surface imaged in (a) and (b).

such as $\text{Nd}_2\text{Fe}_{14}\text{B}$, that cannot easily form closure domains. The increased eccentricity of the spike domains found on surfaces oblique to the (001) surface may be understood as a manifestation of flux minimization for surfaces that contain only a component of the easy direction, as discussed by Goodenough.⁶ No domain contrast was observed on a surface that is parallel to an easy direction, such as a $(hk0)$ surface.

A novel feature of using secondary electrons to image magnetic materials is that the demagnetizing stray fields present at the material's surface can be viewed three dimensionally, as shown in Figs. 3(a)–3(c). The (001) surface of the sample is tilted such that there is a shallow angle with respect to the optical axis of the microscope. The fringing fields appear as parallel rows of hillocks separated by narrow troughs, suggesting that the origin of the stray fields are the parallel plate/maze domains that extend through the bulk of the crystal, not the surface spike domains.

FIG. 3. (a) Image of the surface stray fields emanating from the crystal. (b) Enlargement of (a), illustrating the stray-field trough and hillock formations; (c) end-on view of surface flux from two crystallographic facets.

Generally, the image quality of magnetic contrast generated by F_{Lorentz} in SEM is generally poor. Both extensive theoretical⁷⁻⁹ and experimental¹⁰⁻¹² studies have been conducted to seek optimal parameters to improve the image quality. In most cases sample surface decoration^{13,14} or extensive image processing¹⁵ is still required. Recent work by others indicated that it was necessary to externally alter the detection system of the secondary electrons; Szmaja¹⁵ introduced an aperture in front of the secondary electron collector to act as an energy selector. Instead of having such an attachment inside the specimen chamber, the JEOL 6400 SEM is equipped, at the factory, with an automated bias adjustment circuitry to the collector which itself then acts as an energy filter. It should be borne in mind that this technique is most suitable for materials with a large, perpendicular magnetization vector because the resolution of the image is proportional to the Lorentz force of the excitation volume, as well as inversely proportional to the working distance between

the detector and the specimen. However, materials with smaller magnetizations relative to $\text{Nd}_2\text{Fe}_{14}\text{B}$ may be imaged, with comparable resolution, using a smaller electron accelerating voltage.

A high density of reversed spike domains are observed on all surfaces except the easy-plane (110) surface, with a resolution on the order of $1\text{ }\mu\text{m}$. This technique may prove to be useful for a quick and relatively simple characterization of a magnetic material surface condition and domain structure. It has the additional advantage over other magnetic domain imaging techniques in that a large area of material may be examined at one time. The simplicity of the technique and the ready adaptability of the SEM to such modifications as *in situ* current and magnetic field application may allow direct simulations and observations of a magnetic material operational performance.

A flexible two-dimensional phase correction for interleaved echo-planar imaging reconstruction

Haiying Liu^{a)}

Department of Radiology, University of Minnesota, Minneapolis, Minnesota 55455

Interleaved echo-planar imaging (EPI) is a fast clinical magnetic resonance imaging (MRI) scheme that obtains multiple echoes with a proper phase encoding (PE) strategy to generate multiple k -space PE lines. Since these PE data lines are from different echoes that may carry different phase and amplitude errors originating from the static magnetic field inhomogeneity and nuclear spin relaxation, to form an image free of artifacts, both phase and amplitude errors need to be compensated properly. To address this issue, we have developed a general image reconstruction technique which is capable of accomplishing two-dimensional (2D) phase correction for image reconstruction of interleaved EPI data. In this technique we formulated the reconstruction as a problem of finding an optimal solution to a set of linear algebraic equations corresponding to an imaging measurement. The phase errors, as well as other constraints, can be incorporated into these equations. The final solution can be obtained by inverting the coefficient matrix of the equation via a complex singular value decomposition (SVD) procedure, free of k -space data gridding. 2D phase corrected images have been successfully reconstructed using a set of imaging data acquired on a clinical MRI scanner. The significance of the work is that it has demonstrated that the 2D spatial phase correction can be accomplished for a set of interleaved EPI acquisition. Also, this is a flexible image reconstruction method for further improving the resulting image quality. © 1998 American Institute of Physics. [S0021-8979(98)30511-3]

Interleaved echo-planar imaging (EPI) has already been widely used for many clinical magnetic resonance imaging (MRI) exams to achieve both short scan time and high spatial image resolution since it was first proposed by Rzedzian,¹ Farzaneh,² and Cho,³ then implemented by McKinnon⁴ and Butts⁵ in the early 1990's. The interleaved EPI technique obtains multiple echoes at different echo times (TE) for each repetition interval or each excitation with an oscillatory readout gradient waveform as shown in Fig. 1. This allows obtaining multiple k -space encoding lines per shot or per MR signal excitation (Fig. 2). Since in the technique the phase encoded data lines are coming from different echoes corresponding to different echo times due to main field inhomogeneity and spin relaxation, these different echoes may carry different errors in both amplitude and phase. To form an image free of artifacts, both phase and amplitude errors, as well as discontinuities, need to be compensated either by sliding the data sampling window³⁻⁵ or performing phase correction. It is known that the acquisition scheme using nonsliding data sampling window for the EPI acquisition using multiple shots suffers the same problems. However, such an approach for EPI with an appropriate phase correction scheme promises a relatively simple alternative in practice. Many phase correction methods have been developed for matching data of different k -space segments. Due to the intrinsic difficulty of the problem, most of them are only one dimensional in nature. Actual phase error due to susceptibility at a given echo time is often spatially two dimensional.

To obtain an image of an object, such as the human body, the object is placed in a very strong and uniform static magnetic field typically 1.5 T generated by a cylindrical shaped superconducting magnet, a sinc function modulated radio-frequency (rf) pulse is applied to the object from a rf antenna in concert with a slice select (SS) magnetic field gradient to excite proton nuclear spins within a thin slice of the object at a desired orientation. These excited spins are then spatially encoded according to their in-plane locations using two sets of magnetic field gradients varying linearly in space along two orthogonal orientations (Fig. 1). The corresponding spatially encoded MR signals are detected, amplified, demodulated, digitized, and transferred to a computer for storage, processing, and display. A digital image representation of the object is formed from these MR signals

FIG. 1. The gradient and rf profiles for a four-echo interleaved EPI pulse sequence. E1, 2, 3, 4 denote four different MR gradient echoes of the imaging sequence, respectively.

^{a)}Electronic mail: Haiying.Liu-1@tc.umn.edu

FIG. 2. Traversal of the four-echo interleaved EPI data acquisition in k -space. The rectangular k -space area is partitioned into four equal segments which are filled by different echoes, respectively. Index 1 and 2 denote the k -space trajectories of first and second excitation, respectively.

known as raw data that cover an area in 2D k space sufficiently large and dense for a required spatial resolution and field of view (FOV) using discrete Fourier transformation (DFT) or in most cases fast Fourier transformation (FFT). Although FFT based reconstruction is the most common method in MRI, it becomes less flexible for accomplishing a 2D phase correction. To address this problem, a 2D image reconstruction for the multiple shot EPI technique can be formulated as a numerical problem of finding a solution to an integral or linear equation as shown below:

$$\int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} [\rho(x,y) + n(x,y)] e^{i[\varphi_J(x,y) + k_x x + k_y y]} dx dy = s_J(k_x, k_y), \quad (1)$$

where $\rho(x,y)$ represents the unknown spin density function for a finite size object to be reconstructed, $n(x,y)$ denotes a noise contribution, $\varphi_J(x,y)$ is the 2D phase error induced by the static magnetic field inhomogeneity at the corresponding echo time indexed by J , and $s_J(k_x, k_y)$ denotes a measured raw data point corresponding to the k -space coordinate pairs of k_x, k_y commonly known as for the read, phase directions, respectively. In digital imaging, measured values for k_x, k_y are discrete and uniformly spaced. They can be related to the read $G_{rd}(t)$ and phase $G_{pe}(t)$ gradient profiles as follows:

$$k_x = \gamma \int_0^{TE} G_{rd}(t) dt, \quad (2)$$

$$k_y = \gamma \int_0^{TE} G_{pe}(t) dt,$$

where γ is the gyromagnetic ratio, and t denotes the sequence timing with the center of rf excitation as zero. For completely encoding an object in discrete digital image representation which consists of N row by N column pixels and covers a squared field of view of $L \times L$, the largest spacing Δk between neighboring points in k space is $2\pi/L$, and the maximum value k_{\max} is $N/2 \Delta k$. Furthermore, the noise term $[n(x,y)]$ can be assumed to be spatially and temporally uncorrelated. To seek an optimal solution for the density func-

tion $\rho(x,y)$ satisfying Eq. (1) we constructed a cost functional from a total squared error between a prediction and the measurement as follows:

$$E = \sum_{J,k \in K_J} |s_J(k_x, k_y) - \hat{s}_J(k_x, k_y)|^2, \quad (3)$$

where the integer number J denotes an echo index ($J = 0, 1, \dots, N_{\text{echo}} - 1$), k stands for $\{k_x, k_y\}$, K_J represents an area or a segment in the k space covered by the J th echo data, and “ \hat{s} hat” denotes a predicted k -space data point. Let us define this predicted k -space data point in the context of discrete image representation as

$$\begin{aligned} \hat{s}_J(k_x, k_y) &= \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \rho(x,y) e^{i(\varphi_J + k_x x + k_y y)} dx dy \\ &\approx \Delta x \Delta y \sum_{x=-L/2}^{+L/2} \sum_{y=-L/2}^{+L/2} \rho(x,y) e^{i(\varphi_J + k_x x + k_y y)}, \end{aligned} \quad (4)$$

where both x and y denote a set of discrete positional variables corresponding to each image pixel. Then we seek a solution for the spin density function that minimizes the cost functional. In this framework, a best estimation for the object spin density $\rho(x,y)$ was achieved through an optimization procedure in which the error functional was minimized with respect to the variation of $\rho(x,y)$. After some algebraic reductions, we derived a set of linear equations for the subsequent image reconstruction assuming that the size of image is L :

$$\begin{aligned} \sum_{y'} \rho(x, y') \sum_{J, k_y \in K_J^y} e^{i[\varphi_J(x, y') - \varphi_J(x, y)]} e^{ik_y(y - y')} \\ = \sum_{J, k_y \in K_J^y} e^{-i\varphi_J(x, y)} e^{-ik_y y} s_J(x, k_y), \end{aligned} \quad (5)$$

where y represents a set of discrete y coordinates within a finite range, the division of the y coordinate depends on the resolution limit, $s_J(x, k_y)$ is the data array $s_J(k_x, k_y)$ after performing a first discrete Fourier transformation with respect to k_x . For a fixed x coordinate, the system equation above for image reconstruction can be expressed in a form of matrix equation, $H\rho = f$, where H denotes a complex squared matrix whose elements are given by

$$H_{mn} = \sum_{J, k_y \in K_J^y} e^{i[\varphi_J(x, y_m) - \varphi_J(x, y_n)]} e^{ik_y(y_n - y_m)}. \quad (6)$$

ρ is the unknown column intensity vector for the image or spin density function of the object, whose m th element is defined as

$$\rho_m = \rho(x, y_m), \quad (7)$$

and f denotes an auxiliary complex column vector, whose n th element can be computed from the measured MR signal $S(x, k_y)$ as

$$f_n = \sum_{J, k_y \in K_J^y} e^{-i\varphi_J(x, y_n)} e^{-ik_y y_n} s_J(x, k_y). \quad (8)$$

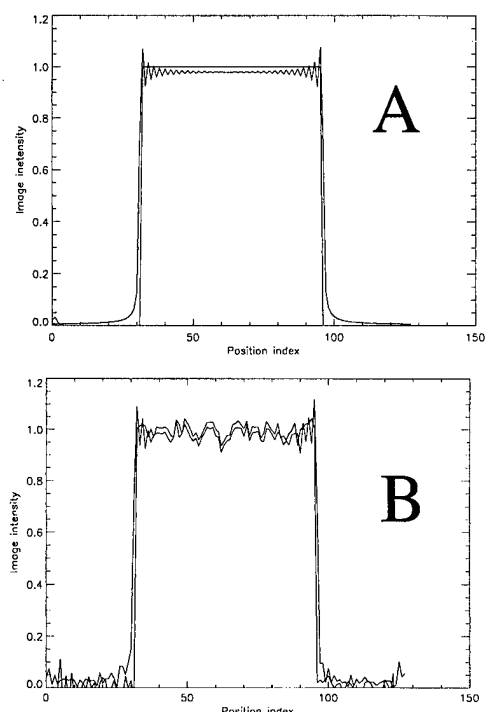

FIG. 3. Image of a 1D rectangular shaped object reconstructed using FFT and ART techniques. The profile showing ripples at the edges corresponds to the FFT technique. The almost perfect profile corresponds to the ART technique with 2D phase correction (A: without addition of noise; B: with noise).

The H matrix carries the information of a specific encoding strategy, as well as the phase and amplitude errors. Generally, for nonzero phase error, the matrix element $H_{m,n}$ is no longer shift invariant or only a function of parameter $(m-n)$. Therefore, a shift invariant point spread function does not exist for the problem. In practice, all the required phase error information can be estimated from a set of low spatial resolution image acquisitions for all echoes using the same imaging sequence except that all the phase encoding blips are modified. Since the typical phase errors at different echo times in MRI are low spatial resolution, this estimation for the phase error is often adequate. The optimal solution for the discrete image representation can be written symbolically as

$$\hat{\rho} = H^{-1}f, \quad (9)$$

where H^{-1} denotes an inverse of the complex H matrix, assuming that the inverse of H matrix does exist. In practice, this H matrix was first decomposed into a product of three matrices using a robust method known as complex singular value decomposition (SVD) as shown below:

FIG. 4. A typical transverse MR-ART image of human brain (A) in comparison with that of DFT (B) at 1.5 T using an interleaved EPI sequence with an effective TE of 30 m.

$$H = UWV^T, \quad (10)$$

where U and V are two complex unitary matrixes, and W is a diagonal matrix. The inversion of the H matrix was easily obtained by carefully inverting the stable (or nonzero) elements of the diagonal W matrix.

Numerical simulations have been performed on a computer to validate the new 2D MR algebraic reconstruction technique (MR-ART). First, we numerically generated a set of testing data from a known 1D object function mimicking a four-echo multiple shot EPI technique. Furthermore, we incorporated a set of known, spatially dependent phase errors in these four echoes. Using the new image reconstruction method, the phase corrected image data were obtained and found to be identical to the known object data as shown in Fig. 3. When a noise was added, the resulting MR-ART image was sharper at various edges. Results showed that this method was robust in both image reconstruction and phase correction. We have successfully applied the new technique to interleaved spin echo (SE) EPI data obtained from a 1.5 T MRI system. This EPI sequence consists of four gradient echoes after a refocusing rf pulse. For a standard 2D imaging, four gradient echoes were phase encoded independently for covering four contiguous segments in k space corresponding to 256×256 matrix size. For 2D phase correction, four low spatial resolution (along phase encoding) data sets were obtained for all four echoes using a set of common phase encoding steps. Figure 4 displays a typical image from one of the human head imaging studies.

Metallic needle artifacts in magnetic resonance imaging

Haiying Liu^{a)}

University of Minnesota, 420 Delaware Street, SE, Minneapolis, Minnesota 55455

A better understanding of the appearance of a biopsy needle and its image artifacts as well as its interaction with various sequence parameters in magnetic resonance (MR) imaging is beneficial for its application in MR image guided surgical procedures. A standard analytical solution to an infinite long cylindrically shaped object immersed in a uniform magnetic field has been used to predict MR image artifacts. In a more practical setting, we investigated the characteristics of MR image artifacts associated with a finite length metallic needle, specifically at the tip of a biopsy needle when it is approximately parallel to the main magnetic field. The origin of the needle tip artifact, which is exhibited as a blooming ball, was studied using MR imaging techniques and numerical simulation employing finite element method. Satisfactory agreement between theory and experiment has been achieved. Results showed that the image artifacts associated with biopsy needle are present and dependent on MR imaging parameters, but the artifacts can be reduced if optimal imaging parameters were used. © 1998 American Institute of Physics. [S0021-8979(98)37311-9]

INTRODUCTION

The unprecedented interests in using MRI for guidance and monitoring of percutaneous minimally invasive interventions have been driven by magnetic resonance (MR) excellent soft tissue contrast, multiplanar capabilities and sensitivities to temperature, flow, susceptibility, etc.,¹⁻³ and also made practical by the recent advances in MR and related technologies. The possibility of an induced magnetic force and an image artifact of a biopsy needle during interventional MRI have long been two primary concerns for the safety of MR image guided surgical procedures and the quality of visualization and positional accuracy of the resulting images.^{1,2} Today, many of these obstacles have been overcome with the introduction of new materials such as titanium alloys and carbon fiber composites. Although metallic needles tend to have more severe image artifacts than those of carbon fiber, these metallic needles are often preferred because of clinical issues such as performance and visibility as well as practical issues such as machinability and production cost. As interventional MRI is steadily pushing itself to more delicate neurological surgical procedures where a much higher spatial precision is demanded, thus, any image artifact associated with the surgical instrument becomes an even more crucial problem. For interventional applications at high field (>1.0 T), the requirements for these MRI compatible devices (needles), are more stringent in terms of the need to control mechanical forces/torques and imaging artifacts. Suitable materials for these needles as well as other surgical devices are generally the nonferromagnetic, chemically inert, biocompatible, nontoxic materials such as titanium alloys, carbon fiber composites, copper, nonferromagnetic steel, etc.

THEORY

Disturbance of the uniform static magnetic field due to a cylindrically shaped object whose magnetic susceptibility

differs slightly from that of the surrounding can be predicted, and the resulting MR image distortion can be estimated. The image intensity artifacts and geometric distortion associated with a biopsy needle can to some extent be understood by modeling a biopsy needle as an infinitely long solid cylinder in a uniform static magnetic field. A general analytical expression for the resulting external field perturbation can be obtained by solving a simple static magnetics problem whose geometry is shown in Fig. 1:

$$\delta \mathbf{B}_{\text{ext}} = B_0 \frac{\mu_n - \mu_t}{\mu_n + \mu_t} \frac{a^2}{\rho^2} \sin \theta (\cos 2\psi \mathbf{e}_p + \sin 2\psi \mathbf{e}_q), \quad (1)$$

where θ is the angle between z axis and the long axis of the needle, the long axis of the needle is assumed to be in the $y-z$ plane, B_0 denotes the strength of the static uniform magnetic field whose direction is along the z direction as shown in Fig. 1, μ_n and μ_t represent the magnetic permeability of the needle material and surrounding tissue, respectively, a is the radius of the needle, p and q denote two axes orthogonal to the long axis of the needle, ρ is the radius of the observation point within the plane defined by p and q , ψ is the angle between the vector ρ and the p axis, and \mathbf{e}_p and \mathbf{e}_q are two unit vectors denoting the directions of p and q .

FIG. 1. Schematic of a solid metallic needle placed in an angle to the direction of the main magnetic field denoted by B_0 . The axis of the needle is assumed to be in the plane defined y and z axes.

^{a)}Electronic mail: haiying.liu-1@tc.umn.edu

axes. Inside the cylindrically shaped needle, the magnetic field error can be found analytically to be spatially uniform as given below:

$$\delta B_{in} = B_0 \left(\frac{\mu_n - \mu_t}{\mu_n + \mu_t} \sin \theta e_p + \frac{\mu_n - \mu_t}{\mu_t} \cos \theta e_l \right). \quad (2)$$

The magnetic susceptibility induced geometrical image distortion can be described as a pixel shift along the readout direction on the resulting MR image. This positional shift is inversely proportional to the readout gradient strength or the data sampling bandwidth for distorted coordinates which can be computed as follows:

$$\begin{aligned} X^d &= X + \frac{\delta B_{ext}}{G_{rd}}, \\ Y^d &= Y, \\ Z^d &= Z + \frac{\delta B_{ext}}{G_{sl}}, \end{aligned} \quad (3)$$

where X and Y denote the readout axis and phase axis of an image plane, respectively, Z is the slice axis, δB_{ext} is the static main magnetic field error, and G_{rd} and G_{sl} denotes the strength of the imaging readout gradient and slice select gradient, respectively. Due to the locally induced field inhomogeneity, the image intensity attenuation for a gradient echo sequence is determined by a transverse inhomogeneity induced intravoxel relaxation time constant denoted by τ which is proportional to the local field gradient ($\propto \nabla B$).

In the practical setting, these theoretical results for such an ideal case have severe limitations. For example, when a biopsy needle is placed parallel to the main static magnetic field, the resulting image artifact becomes minimal along the sheath of the needle, but exhibits a blooming ball shaped intensity void at its tip, which is not anticipated by the simple model. The immediate concern is that the visualization of the tip location may be obscured by this image artifact. In particular, the fact that a real needle is finite in length has not been fully considered in the model.

According to static magnetism theory, for a problem involving zero external macroscopic current, a magnetic scalar potential as well as magnetic charge can be introduced. The surface magnetic charge density (σ_m) for a rounded needle tip as well as the bulk charge density (ρ_m) can be computed from the magnetization M of the needle. Since the magnetization of the needle shaped object in a strong and uniform magnetic field is fairly uniform in the middle, there exists no bulk charge density inside the needle away from the ends. The charge exists predominantly on the surface and the ends. The bulk magnetization $M = \chi H$, where χ is the magnetic susceptibility [for titanium (Ti) 1.8×10^{-4} , water -0.88×10^{-5}] and H is the magnetic field intensity. At the end of the needle, H becomes spatially nonuniform due to the locally induced charges. Although the exact analytical solution for H is difficult to obtain, its numerical solution can be relatively easily obtained using a finite element method (FEM). By integrating the effect of both the surface charge over the surface area of the needle and the bulk charge over the volume of the needle, the total perturbation on the mag-

netic scalar potential in the vicinity of the tip of the needle can be obtained numerically for arbitrarily complex geometries:

$$\Phi(\mathbf{r}) = \frac{1}{4\pi} \int \frac{\sigma_m(\mathbf{r}')}{|\mathbf{r}' - \mathbf{r}|} dS' + \frac{1}{4\pi} \int \frac{\rho_m(\mathbf{r}')}{|\mathbf{r}' - \mathbf{r}|} dV', \quad (4)$$

where \mathbf{r} denotes the coordinates for an observation point and \mathbf{r}' denotes the source coordinates. The perturbation on the magnetic flux density external to the needle can be obtained by taking the gradient of the resultant magnetic scalar potential. An axisymmetric FEM model with a set of proper boundary conditions has been constructed for simulating the static magnetic behavior of a needle in a uniform magnetic field. From this model, using FEA software, we obtained the values for the internal and external H field from which the bulk magnetization (M) was derived. From M , both bulk and the surface magnetic charge densities can be determined. The overall magnetic flux density disturbance can be obtained at arbitrarily high spatial resolution by integration using the expression shown above. Starting from the resulting field perturbation of the static uniform main magnetic field, various MR image artifacts, such as an image intensity void and an image geometric distortion, can be numerically simulated and predicted for different imaging techniques.

MATERIALS AND RESULTS

A nonferromagnetic stainless steel needle with a flat tip was used in our imaging experiments. All imaging experiments were conducted on a Philips 1.5T clinical whole body MR scanner (ACS-NT, Best, Netherlands). An imaging phantom, which contained the needle and a nonmagnetic grid structure immersed in water, has been constructed for studying the image artifact associated with a biopsy needle. For better signal to noise ratio, a receive-only head coil was used for the imaging experiments. The high resolution 3D field-echo (FE) and spin-echo (SE) images at multiple data sampling bandwidth were obtained with a FOV of 20 cm and data sampling matrix size of 256×256 .

When the needle was placed perpendicular and parallel to the direction of the main magnetic field, an arrowhead and

FIG. 2. A coronal 2D spin echo image of a MR compatible stainless steel needle with the readout gradient placed vertically. The main magnetic field direction is vertical. Imaging parameters are: FOV=10 cm, slice thickness=5 mm, TR/TE=550/9.5 ms, flip 90, image matrix size 128×128 .

FIG. 3. Two coronal 2D spin echo images at the exact same slice position through the needle with the readout gradient polarity vertically up (left-hand side) and vertically down (right-hand side). The main static magnetic field direction is vertical.

ball-shaped image artifact appeared on the resulting MR images of 3D field-echo technique as shown in Figs. 2 and 3, respectively (readout is along the main field direction). For the perpendicular case, the expected arrow shaped appearance due to the geometric distortion around the needle stem could be simulated.³ In the case where the needle is parallel to the main field, the image artifact in the direction normal to the axis of the needle becomes minimal in the middle of the needle stem, but the size of the intensity void at the tip of the needle appears significantly larger than the diameter of the needle. The actual location of the needle tip was at the center of the reference square grid, whose dimension was 15 mm×15 mm. Generally, we found that the center of the artifact coincided with the true needle tip location. Furthermore, as the readout gradient is inverted, the appearance of the artifact is quite different [Fig. 3(B)]. The resulting image artifact tends to collapse to a small perpendicular line at a level corresponding to the tip of the needle. As the readout gradient was tilted with respect to the needle, the resulting artifact shape followed the readout direction. For example when the needle was placed at a 40° angle with respect to the

FIG. 4. Magnetic field intensity (H) and flux density along a metallic needle axis at 1.5 T. Only one end of the needle is shown.

FIG. 5. Two numerically simulated coronal 2D spin echo images through the MR compatible stainless steel needle with the readout gradient polarity indicated. The main magnetic field direction is horizontal.

z axis while keeping readout parallel to the main field, we observed that the needle stem appeared wider as the angle increased. In addition, there still existed the same tip artifact along the readout direction. When the phase encoding gradient was set to be perpendicular to the needle, the size of the artifact was reduced. The magnetization and field were numerically simulated, the field intensity H and flux density B along the needle long axis are shown in Fig. 4. Using the needle magnetization as an input, the field perturbation external to the needle was computed at high spatial resolution. Based on the calculated error field, an imaging experiment can be simulated assuming everything else is perfect. Simulated images qualitatively reproduced the observed image artifact as shown in Fig. 5. Figure 4 shows that the error magnetic field intensity (ΔH) above and below the tip are pointing in opposite directions. This is consistent with the fact that the magnetic charge is mostly localized at the surface of the tip. At 1.5 T, based on a rough estimation assuming the needle is uniformly magnetized, the resulting field perturbation on the surface of a nonferromagnetic metallic needle tip can be as large as 6 kHz.

CONCLUSION

We have shown the overall appearance of the MR image artifacts associated with the tip of a biopsy needle for various relevant imaging parameters, and demonstrated that these image artifacts originate from both rf off resonance effects and geometric distortion. A theoretical explanation has been introduced and validated using the MR imaging results. Practical experience indicates that moderating image artifacts to some extent enhances the visibility of the needle. Understanding the characteristics of the needle artifact and interaction with imaging parameters can help in not only optimizing the imaging parameter and technique to reduce the potential image artifact but also in interpreting the artifact properly.

The magnetic behavior of MnZnTi and NiZn ferrite films, deposited by laser ablation, is studied comparatively to that of the bulk material, using a vibrating-sample magnetometer (VSM), transmission, and conversion electron Mössbauer measurements. Both the VSM and Mössbauer analysis show that the films exhibit the single phase pattern of the target material. Mössbauer hyperfine field values for films are close to those found for the bulk, and this accounts for the same saturation magnetization values determined by VSM. Laser ablated films exhibit a higher coercive field, which is explained in terms of the crystallite size distribution, with average values of 300–600 nm, as estimated from the Mössbauer line broadening. © 1998 American Institute of Physics. [S0021-8979(98)48911-4]

I. INTRODUCTION

MnZnTi and NiZn ferrite films have been deposited by laser ablation with stoichiometries close to the target^{1–4} and, most importantly, without postdeposition heat treatments to form the spinel structure, as required by other synthesis processes such as rf or dc sputtering. As laser ablation deposition is a “dry-processing” technique, compatible with other approaches currently used in modern technology, of continuing interest for producing ferrite films, the magnetic properties of the films must be understood within the context of the requirements for potential applications. However, there have been few, if any, systematic studies that correlate the magnetic quality of the ferrite films with the spinel microstructure. In this article we correlate the saturation magnetization and the coercive field for the MnZnTi and NiZn ferrite films with the hyperfine parameters of their conversion electron Mössbauer spectra (CEMS). We also compare the magnetic properties of the laser ablated films with those of the bulk material.

II. EXPERIMENTAL PROCEDURE

The MnZnTi and NiZn ferrite targets were prepared by conventional powder ceramic techniques⁵ with nominal compositions $\text{Mn}_{0.66}\text{Zn}_{0.26}\text{Ti}_{0.02}\text{Fe}_{2.06}\text{O}_4$ and $\text{Ni}_{0.35}\text{Zn}_{0.65}\text{Fe}_2\text{O}_4$. Laser ablation was performed, as described elsewhere,^{1–4} inside a stainless-steel vacuum chamber, with a base pressure of 10^{-5} mbar, using an excimer laser source Lambda Physik model LPX 100, operated with XeCl* active mixture ($\lambda = 308$ nm), giving 30 ns, 65–75 mJ pulses, at a repetition

rate of 21 Hz. A high repetition rate was desirable from the standpoint of minimizing the concentration of background impurities in the films. The target was rotated at a frequency of 0.2 Hz for uniform target wear and to minimize droplets on the substrate, which was located at a distance of 4 cm from the target surface and parallel to its surface. The ferrite films were deposited onto high silicon content glass substrates, at substrate temperatures of 850 °C and at oxygen pressures of 0.15–0.2 mbar. This substrate temperature ensures high atomic mobility, so improving film crystallinity. After deposition, the films were cooled slowly to room temperature by turning off the power to the substrate heater and raising the pressure in the vacuum chamber to 2 mbar of oxygen.

The relative elemental concentrations were used to estimate the atomic composition of the deposited films, by considering their values normalized to the nominal composition of the targets. We have found an average composition $\text{Mn}_{1-x-y-d}\text{Zn}_x\text{Ti}_d\text{Fe}_{2+y}\text{O}_4$ with $x=0.2\text{--}0.22$, $y=0.13\text{--}0.15$, $d\sim 0.01$, and respectively, $\text{Ni}_{1-x-y}\text{Zn}_x\text{Fe}_{2+y}\text{O}_4$ with $x=0.58\text{--}0.64$ and $y=0.08\text{--}0.1$. As the error in the determination of the areas of the peaks in the x-ray energy spectrum exceeds the Ti content in the bulk material, the average composition of the films may be assumed to be satisfactorily stoichiometric with respect to the targets. The Mn, Ni, Zn, and Fe concentrations of our films remained almost constant irrespective of the deposition conditions, within the error of the energy dispersive spectroscopy (EDS) system, although the data suggest a slight deficiency of Zn (a few atomic percents) in the films as compared with the original targets.

The magnetization curves were measured for the target material and the films, at room temperature, by a vibrating

^{a)}Electronic mail: amado@fisf.fc.up.pt

FIG. 1. VSM magnetization loops of MnZnTi ferrite target (a) and film (b), measured in-plane and out-of-plane.

sample magnetometer (VSM). Transmission Mössbauer spectra has been obtained from the powdered target material, on a constant acceleration spectrometer with a $^{57}\text{Co}/\text{Rh}$ source. The CEMS spectra were recorded from the films using a room temperature detector.⁶ The integrated Mosswin program⁷ has been employed to calculate the spectral parameters and the crystallite size distribution for the films.

III. RESULTS AND DISCUSSION

Typical in-plane and out-of-plane magnetization curves are shown Fig. 1 for the MnZnTi ferrite target and films. The saturation magnetization was determined for films to be within a few percent of the value for the bulk material, namely in the range $(220\text{--}280) \times 10^5 \text{ J/T/m}^3$ ($220\text{--}280 \text{ emu/cm}^3$), and this is consistent with stoichiometric ferrites. However, the coercive field H_c for the films, with values in the range of 6400 to 14300 A/m (20 to 45 Oe), is obviously larger than that found for the targets. This suggests a strong influence from the film microstructure, and is likely to indicate the presence of crystallite shape anisotropy.⁸

The room temperature transmission and CEMS spectra for the MnZnTi target material and film, respectively, are plotted in Fig. 2. The computed spectrum of the bulk material contains one sextet for the tetrahedral (A) iron, which has the highest effective fields $H(A) = 40.9 \text{ T}$, another sextet for the octahedral (B) iron, $H(B) = 38.1 \text{ T}$, and an additional subspectrum ($H = 34.3 \text{ T}$) assigned to $\text{Ti}^{4+}\text{Fe}^{2+}$ pairs, formed by fast electron transfer between multivalent iron and

FIG. 2. Room temperature transmission Mössbauer spectrum from the MnZnTi target and CEMS spectrum from the laser ablated film.

titanium ions.⁵ The CEMS spectra from the film indicate slightly smaller values of the magnetic fields at the two sites, $H(A) = 39.5 \text{ T}$ and $H(B) = 36.2 \text{ T}$, which is consistent with the magnetization behavior [see Figs. 1(a) and 1(b)]. The relative iron concentration at the octahedral site decreases upon ablation, and this is likely to be related to the Zn deficiency, as indicated by elemental analysis. There is a line-width increase in the CEMS spectra with respect to the transmission data, which allows an estimate of the crystallite size distribution, as described before.⁹ The average crystallite size is found to be in the range of 300–600 nm, in agreement with the atomic force microscope (AFM) image analysis.³ This crystallite size is smaller than in the bulk material, and results in increasing the number of low angle grain boundaries, which act as pinning sites for domain walls and are responsible for larger H_c values.⁸

From the magnetization curves of NiZn ferrite, shown in Fig. 3, the film saturation magnetization was found to be $660 \times 10^5 \text{ J/T/m}^3$ (660 emu/cm^3), which is close to the value for the bulk material, as expected from stoichiometric NiZn ferrite. The coercive field of about 25.5 kA/m (80 Oe), is larger than the values found for the target, and this can be also attributed to a decrease in the crystallite size. This conclusion is supported by the Mössbauer data analysis.

The transmission spectrum from the NiZn target material shows typical relaxation features, which appear as two sextets, $H(A) = 36.4 \text{ T}$ and $H(B) = 30.6 \text{ T}$, and a quadrupole split doublet ($\Delta E_Q = 1.31 \text{ mm/s}$, $IS = 0.35 \text{ mm/s}$), indicating

FIG. 3. VSM magnetization loops of NiZn ferrite target (a) and film (b), measured in-plane and out-of-plane.

thermally excited domain wall oscillations.¹⁰ These parameters are close to those previously reported¹¹ for the same range of Zn concentration ($x=0.65$). The corresponding (CEMS) parameters of the film, $H(A)=35.7 \text{ T}$ and $H(B)=30.3 \text{ T}$, are consistent with the saturation magnetization data obtained by VSM. The smaller concentration of the quadrupole doublet in the CEMS spectrum, corresponding to almost the same x , can be explained on account of a lower density of the film material¹⁰ (Fig. 4). In other words, our film should be regarded as having some concentration of vacancies and voids, yielding a lower average density. Although such free spaces are expected to result in high-temperature quenched samples, the morphology analysis⁴ indicates that we are not dealing with macroporosities that unfold on the surface. This result is also consistent with the increased coercive field values found for the films (see Fig. 3).

IV. CONCLUSION

The VSM and Mössbauer analysis of the MnZnTi and NiZn ferrite targets and laser ablated films indicate that the films exhibit the single phase pattern of the bulk material. The hyperfine field values for films are close to those found for the targets, and this accounts for the similar range, determined by VSM, for the saturation magnetization values. The higher coercivity of laser ablated films is consistent with the

FIG. 4. Room temperature transmission Mössbauer spectrum from NiZn target and CEMS spectrum from the laser ablated film.

crystallite size distribution, with average values of 300–600 nm, as estimated from the spectral line broadening. A satisfactorily qualitative explanation of the magnetic properties is obtained on taking proper account of both the intrinsic properties, such as stoichiometry, of which the saturation magnetization and hyperfine fields are mainly dependent, and the extrinsic properties, like the crystallite size, with direct influence on the coercive field and the line broadening of CEMS spectra.

Structure and soft magnetic properties of sputter deposited MnZn-ferrite films

M. F. Gillies,^{a)} R. Coehoorn, and J. B. A. van Zon
Philips Research, Prof. Holstlaan 4, 5656 AA Eindhoven, The Netherlands

D. Alders
Department of Physics, Eindhoven University of Technology, P.O. Box 513, 5600 MB Eindhoven, The Netherlands

In this paper we report the soft magnetic properties of thin films of sputtered MnZn ferrite deposited on thermally oxidized Si substrates. A high deposition temperature, 600 °C, together with the addition of water vapor to the sputtering gas was found to improve the initial ac permeability, μ . The highest value obtained was approximately 30. For MnZn-ferrite films with much larger grain sizes, as obtained by deposition on a polycrystalline Zn-ferrite substrate, a μ of 100 was obtained. The results are discussed in terms of the so-called nonmagnetic grain boundary model. © 1998 American Institute of Physics. [S0021-8979(98)53211-2]

I. INTRODUCTION

The growth of thin layers of magnetically soft ferrites such as MnZn or NiZn ferrite has been studied recently by various groups.¹⁻³ This interest is motivated by potential applications such as magnetic thin-film read heads,⁴ cladding layers for thin film inductors,⁵ and microwave acoustic devices.² For most applications, two of the most important parameters are the resistivity of the layer and the ac permeability, μ . While the resistivity is similar to that of the bulk the permeability of the thin ferrite films, on which many authors do not report explicitly, appears to be significantly less. This may be deduced from previously published M vs H loops² where, even when grown epitaxially, the films lack the true softness which characterizes the bulk material.

It has been shown by other authors that the addition of oxygen during deposition can have the effect of improving the softness of a thin film MnZn ferrite.¹ We however, found that this can easily lead to an undesired oxygen rich ferrite. In the case of Fe_3O_4 it was found that the exact oxidation state of sputtered films could be more accurately controlled using H_2O .⁶ In this paper we report the effects on the soft magnetic properties of MnZn ferrite when a small amount of water vapor is added to the sputtering gas.

II. EXPERIMENT

The films were deposited in a Perkin Elmer 2400-8L rf diode sputter system, using Ar at a constant pressure of 0.29 Pa (2.2 mTorr). The background pressure was approximately 1.3×10^{-4} Pa. The substrate temperature during deposition was monitored by a thermocouple inserted into the substrate table and silver paste was used to ensure a good thermal contact. The films were sputtered from a 10 cm diameter $\text{Mn}_{0.51}\text{Zn}_{0.42}\text{Fe}_{2.03}\text{O}_4$ polycrystalline ferrite target which has a bulk μ of approximately 4000. The deposition rate was 0.2 $\mu\text{m/h}$, with a rf power of 250 W, and the films, which were grown on Si substrates with a 0.5 μm pregrown thermal SiO_2

layer, were approximately 0.9 μm thick. The initial ac permeability was measured⁷ using an HP4129A analyzer with an applied ac field of 2.5 A/m.

III. MAGNETIC PROPERTIES

The magnetic properties were studied as a function of two deposition parameters: additional water vapor in the sputtering chamber and substrate temperature. The effect of the presence of an additional amount of water vapor on the soft magnetic properties is shown, for three different substrate temperatures, T_s , in Figs. 1(a)–1(c). In the case of no additional added water vapor, [$p(\text{H}_2\text{O}) = 1.3 \times 10^{-4}$ Pa] an increase in T_s does have an effect on μ , though the maximum value attained was only 16. Upon increasing $p(\text{H}_2\text{O})$ the coercivity H_c [Fig. 1(a)] is reduced, and for a T_s of 550 or 600 °C H_c is approximately 1.6 kA/m with the addition of 0.13 Pa of H_2O . For $T_s = 500$ °C the minimum H_c is approximately 2.8 kA/m.

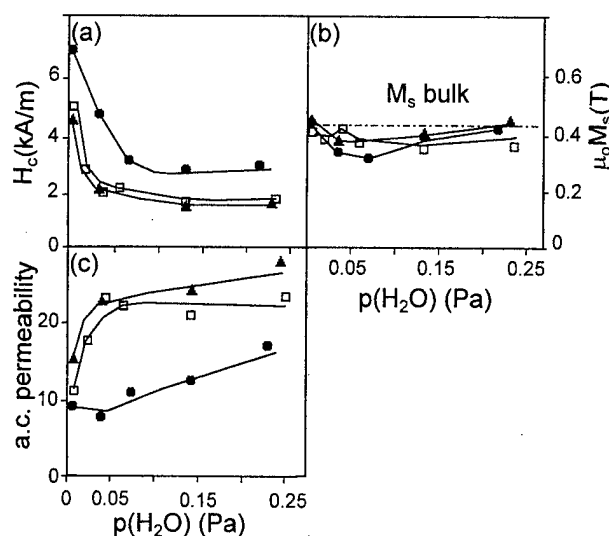

FIG. 1. The effect of the partial water-vapor pressure during sputtering on (a) the coercive field, (b) the saturation magnetization, and (c) the ac permeability of thin ferrite films. Deposited at 500 °C (circles), 550 °C (squares), and 600 °C (triangles).

^{a)}Electronic mail: gillies@natlab.research.phillips.com

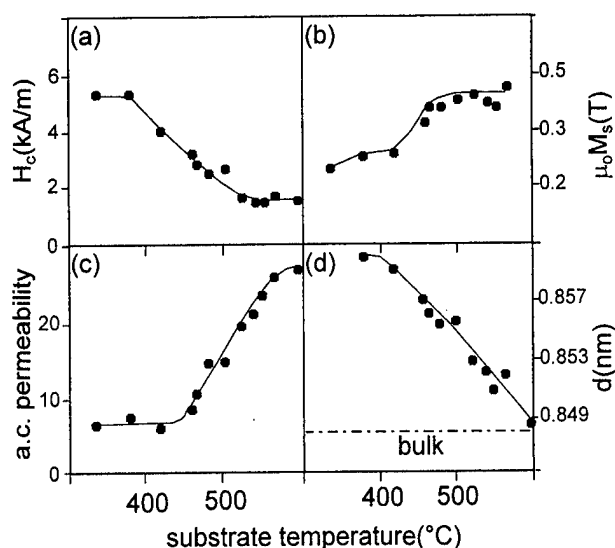

FIG. 2. The effect of a variation in substrate temperature at $p(\text{H}_2\text{O})=0.13$ Pa on (a) the coercive field, (b) the saturation magnetization, (c) the ac permeability, and (d) the lattice parameter of a $0.9\text{ }\mu\text{m}$ MnZn-ferrite film.

The room temperature saturation magnetization, $\mu_0 M_s$, of the sputtered films, Fig. 1(b), is only slightly lower than that of the bulk material (0.44 T).

The ac permeability did not show any rolloff in the 1–13 MHz frequency range and the average value of permeability over this frequency range is what is given in Fig. 1(c). For the different T_s the trend is similar: an increasing $p(\text{H}_2\text{O})$ leads to a higher μ , with the maximum, $\mu \approx 27$, being achieved with a T_s of 600°C and a $p(\text{H}_2\text{O})$ of 0.23 Pa.

While the trends in magnetic properties are independent of T_s the actual values of H_c and μ are not. The magnetic and structural properties (Sec. IV) of the sputtered ferrite were therefore measured for a new series of films where T_s was varied while holding the $p(\text{H}_2\text{O})$ constant at 0.13 Pa. Figure 2(a) shows the influence of temperature on H_c which falls to approximately 1.4 kA/m for T_s higher than 560°C . An increase in T_s also leads to an increase in the $\mu_0 M_s$, Fig. 2(b). Substrate temperatures which are less than 450°C , result in a μ below 10, Fig. 2(c). Above 450°C μ increases rapidly with increasing temperature and at 600°C μ is approximately 27.

IV. STRUCTURAL PROPERTIES

The structural properties of the ferrite were also studied both as a function of $p(\text{H}_2\text{O})$ and T_s . The width and position of the strongest peak, (400), in the θ - 2θ Cu $K\alpha$ x-ray spectra did not show any relation to $p(\text{H}_2\text{O})$ (while T_s was fixed). The stoichiometry of these films, together with those deposited with various substrate temperatures, was checked using x-ray fluorescence, XRF, and electron probe microanalysis, EPMA. For depositions at T_s less than 500°C the composition did not appear to be influenced by $p(\text{H}_2\text{O})$ and was, within experimental error, the same as the target material. For depositions at higher T_s films showed Zn deficiency if deposited without H_2O . The fact that this did not occur in the presence of H_2O may be due to the oxidation of metallic Zn on the surface of the film which would slow

FIG. 3. TEM cross sections of films deposited at (a) 523°C and (b) 604°C .

down any evaporation. For films with a reasonably high μ , such as those deposited at $550^\circ\text{C}/0.13$ Pa water vapor, the stoichiometry was, within experimental error, the same as the target.

From the (400) x-ray diffraction peak positions the lattice parameter perpendicular to the film was determined for films deposited at different T_s , Fig. 2(d). The bulk (target) lattice parameter was 0.848 nm. These experiments, as well as x-ray measurements with a varying direction of the scattering vector and mechanical stress measurements, reveal a reduction in stress for increasing T_s . Due to the strain present in the ferrite films it is not possible to accurately determine the average crystal size via the analysis of x-ray peak widths. This was therefore determined via transmission electron microscopy (TEM) cross sections for films deposited at $T_s = 523, 565$, and 604°C . [The cross sections shown here are only for films deposited at 523 and 604°C (Figs. 3(a) and 3(b), respectively).] While it is possible to discern a columnar structure within all the films it is clear that for a higher deposition temperature the columnar structure is more clearly defined. For the film deposited at $T_s = 523^\circ\text{C}$ there exist imperfections throughout the whole thickness of the film. This is in contrast to films deposited at a higher T_s where the formation of small crystallites only occurs during the initial stage of growth. In the later stages of growth a very distinct columnar structure appears. From the TEM cross sections the estimated average grain sizes for the depositions at 523, 565, and 604°C were 90, 110, and 175 nm, respectively.

V. FILMS GROWN ON A Zn-FERRITE SUBSTRATE

In Sec. IV the values for the approximate grain size of the ferrite films, as determined through TEM, were reported.

From the nonmagnetic grain boundary model⁸ (NMGB model) the relationship between the effective initial permeability, μ_e , the average grain size, D , and the intrinsic permeability, μ_i , of the ferrite within a grain is given by

$$\mu_e = \frac{\mu_i D}{\mu_i \delta + D}, \quad (1)$$

where δ is the width of the nonmagnetic grain boundary zone. Equation (1) implies that for fixed values of δ and μ_i , μ_e can be increased by increasing the grain size. We therefore increased the in-plane grain size of the MnZn-ferrite films by growing on a mechanically polished polycrystalline Zn-ferrite (ZnFe_2O_4) substrate with a grain size of approximately 15 μm . Since the lattice parameter mismatch is less than 0.5% and the thermal expansion coefficients are similar,⁹ Zn ferrite is an ideal substrate on which to grow MnZn ferrite. On account of the substrate being paramagnetic at room temperature the magnetic properties of a MnZn-ferrite film can be measured without a contribution from the substrate. Figure 4 shows a scanning electron microscope photograph of a 0.9 μm thick MnZn-ferrite film, deposited with $p(\text{H}_2\text{O})=0.13$ Pa and $T_s=560$ °C. As can be seen the in-plane grain size is around 15 μm . The film had a H_c of less than 0.1 kA/m and was therefore much softer than those deposited on the Si/SiO₂ substrates ($H_c \approx 1.4$ kA/m for films deposited under identical conditions on Si/SiO₂). The ac permeability of the films deposited on Zn ferrite was 100 ± 5 .

VI. DISCUSSION AND CONCLUSIONS

The improvement in soft magnetic properties by adding water vapor to the sputtering gas was an unexpected result, for which we do not yet have an explanation. We did, however, consider the possibility that the presence of H₂O affects the oxidation state of either the Fe or Mn ions in the ferrite. Using a wet chemical technique it was found that the fraction of Fe²⁺ and Mn³⁺ ions in the films, with and without water vapor, were very similar to that of the target. It could, however, still be possible that the concentration of either Fe²⁺ or Mn³⁺ ions at the grain boundaries is not as in the bulk material and, since these ions can give rise to a large single ion anisotropy in the presence of a crystal field, this could result in grain boundaries with a high anisotropy. The effect of high anisotropy grain boundaries was considered by Pankert¹⁰ and leads to a reduction in permeability.

The effect of the substrate temperature on the soft magnetic properties, which was also observed for films grown on the Zn ferrite, must be related to the increased mobility of the atoms when they arrive at the surface. This has the obvious effect of increasing the grain size which, according to the NMGB model, leads to a magnetically softer film. A higher temperature would also reduce the density of dislocations and other imperfections in the bulk of the grains and could reduce the thickness of the nonmagnetic grain boundary, thereby improving the softness of the ferrite.

The reduction in lattice parameter for increasing T_s , Fig. 2(d), is indicative of a lowering in the total stress which is present in these films (this was also checked using mechani-

FIG. 4. SEM photograph of 0.9 μm MnZn-ferrite film deposited on a Zn-ferrite substrate.

cal stress measurements). Taking the sign of the thermal mismatch between the substrate and the film into account such a behavior cannot be explained in terms of a thermal mismatch alone and there must exist excessive stress within the ferrite film itself. A shift in the lattice parameter, with respect to that of the bulk, is also observed for the MnZn-ferrite film deposited on Zn ferrite. A lowering of total stress for higher deposition temperatures may be responsible, at least in part, for the higher permeability achieved with these temperatures.

As would be expected from the NMGB model the choice of Zn ferrite as a substrate and the consequently larger grain size of the MnZn-ferrite film lead to a higher permeability. If, however, one substitutes into Eq. (1) the average grain size of the film shown in Fig. 4, together with a nonmagnetic grain-boundary thickness of a few nanometers (for the bulk a value of 1.4 nm has been determined⁸) then $\mu_i \approx \mu_e$, where μ_e has been found to be approximately 100. Such a low value of μ_i may be caused by the presence of residual stress in the films though it is important to realize that the cation distribution was not checked in these sputtered layers and that a deviation from the desired distribution could also result in a low μ .

A permeability of 30, as obtained for thin films on Si/SiO₂ is sufficient to utilize these layers as cladding layers for thin film inductors. As a flux guide material in yoke-type thin film read heads⁴ a permeability of 30 is not quite sufficient. Further effort is therefore needed to realize a higher permeability and a lower deposition temperature.

Emission studies of Ba-hexaferrite plume produced by a KrF excimer laser

Optical emission measurements and intensified charge coupled detector images of a plasma generated by the interaction of a KrF excimer laser with a Ba-ferrite target have been used to study the laser ablation deposition of Ba ferrite thin films. Time integrated spectra were collected as a function of distance above the target surface and as a function of oxygen pressure. Temporal profiles showed that close to the target the plume is insensitive to ambient oxygen pressure and at greater distances a much more pronounced influence is observed. Time resolved images of the overall optical plasma emission clearly demonstrated how the presence of oxygen confines the plasma and enhances its emission. © 1998 American Institute of Physics. I. INTRODUCTION

The *M*-type hexaferrites are an important class of materials for microwave, high-density magnetic and magneto-optical (MO) recording technologies. *M*-type Ba and Sr-hexaferrite with perpendicular magnetic anisotropy have been previously grown *in situ* on (001) oriented single crystal substrates of Al₂O₃,¹ yttria stabilized zirconia (YSZ), and Si², using pulsed laser deposition (PLD). Our earlier studies revealed that hexaferrite films prepared from stoichiometric targets at 840 °C, and 0.1 mbar for a target substrate distance of 30 mm exhibited the highest degree of crystalline quality and nearly bulk magnetic and magneto-optical properties. At reduced oxygen pressures (<0.1 mbar) the films, which were grown at 840 °C, displayed an enhanced fraction of in plane oriented (*c*_{||}) crystallites while at increased oxygen pressures

(>0.1 mbar) the surface was populated with outgrowths which also contributed negatively to the perpendicular anisotropy and made the surface rough.

We describe the propagation of excimer laser ablated plasma into background oxygen pressures, used for film growth, as observed by emission spectroscopy and intensified charged coupled detector array (ICCD) photography. The emission characteristics of the plume were correlated with the quality of the Ba-hexaferrite films synthesized by PLD. First, we report on temporally integrated, spatially resolved emission spectra from plasmas along the direction perpendicular to the target surface. The data were collected for plasmas propagating both in vacuum and in an ambient oxygen, from which the composition and state of ionization of the emitting species could be deduced. We have also investigated the effect of oxygen pressure on the spatial and temporal behavior of a number of atomic and ionic species in the plume. Effective species velocities were derived from the time dependent profiles and plasma temperatures were esti-

mated from the integrated line intensity ratios of ionic species. Furthermore, the expansion of the plasma in vacuum and oxygen ambient has been photographed with a gated, intensified CCD array camera system.

II. EXPERIMENTAL PROCEDURES

The apparatus used in the present experiments has been described previously.³ All measurements were carried out on plasmas produced following KrF excimer laser ($\lambda = 248$ nm, full width at half maximum (FWHM)=20 ns) ablation, in vacuum and oxygen pressures up to 0.5 mbar, at a laser fluence of 2 J/cm², with the laser beam incident at 45° to the rotating BaFe₁₂O₁₉ target. Temporally integrated emission spectra were recorded by imaging, at a 1:1 magnification, the luminescent plume onto the entrance slit (25 μ m wide, 3.7 mm high) of a compact spectrograph (Oriol Multispec) fitted with a 1024 element photodiode array (Oriol Intaspec). The plasma was viewed perpendicular to its main expansion direction, *z*. The compact spectrograph/diode array assembly was mounted on a micrometer driven transverse slide enabling the spectrograph slit to select light from sections of the plasma adjacent to the target (*z*<0.5 mm) to sections 30 mm along the *z* axis. The detection system provided wavelength coverage from 350–700 nm at a spectral resolution of ~ 1 nm. All recorded spectra were integrated over 100 consecutive laser pulses, accumulated at a repetition rate of 10 Hz.

For temporally resolved measurements a gated intensified 1024 photodiode array and a digital delay generator (DDG) was employed. This detection system had a temporal resolution of ~ 100 ns and a spectral resolution of ~ 1 nm. All spectra data were corrected for a wavelength variation of the intensified photodiode array system.

Temporally resolved two-dimensional (2D) imaging of the total laser-induced plasma emission of a BaFe₁₂O₁₉ target was performed using a fast gated, ICCD camera system.

III. RESULTS AND DISCUSSION

Figure 1 presents a typical spectrum of the temporally integrated plasma emissions observed 2 mm from the target

FIG. 1. Temporally integrated emission spectrum recorded at 2 mm from a $\text{BaFe}_{12}\text{O}_{19}$ target at a base pressure of 10^{-5} mbar.

surface at a base pressure of 10^{-5} mbar. Only emission lines from Ba and Fe neutrals and singly ionized Ba species were observed. Note that no lines could be assigned to ionized Fe species in this highly ionized region. This is not surprising since Fe^+ does not have any strong emission lines in the studied wavelength range; presumably its presence is obscured by strong overlapping emissions emanating from other species.

Furthermore, no bands attributable to diatomic oxide molecules such as BaO and FeO could be detected either in vacuum or under oxygen atmospheres along the plasma expansion axis. The reaction of Ba with O_2 to form ground-state BaO is exothermic by 0.55 eV for low energy Ba atoms and would occur readily for more energetic Ba atoms within the plume.⁴ The BaO formed may undergo collisional excitation but its weak extended emission band system over the range of 450–750 nm renders identification difficult. The absence of any identifiable strong BaO in the emission spectra is not therefore unexpected.

Conversely, the formation of excited FeO from oxidation reactions of atomic Fe species at the plume oxygen interface is considered unlikely. The reaction of Fe with O_2 is endothermic by 0.92 eV and does not occur for normal collision energies. Some gas phase oxidation might be expected during the earlier energetic phases of plume expansion but the FeO formed could dissociate rapidly (dissociation energy of FeO is 4.18 eV) by collisions with energetic electrons in the high temperature plasma or by single laser photon absorption. It is therefore likely that the ultimate Fe content in the laser deposited films is mainly incident on the growing film in the form of atomic Fe and that appreciable oxidation occurs on the surface.

In the neighborhood of the target surface ($z < 0.5$ mm), Stark broadened ionic and atomic lines were superimposed on a continuum background. The continuous emission, produced from a hot dense core has been reported⁵ during ablation of several materials.

In vacuum the intensities of all species fell off by a factor greater than 10, over the first 10 mm. The decline is

attributed to a reduction in electron impact excitation of the plasma species as the ion and electron number densities decrease due to free expansion into vacuum.

Introduction of oxygen caused a marked enhancement of the emission at all wavelengths. This is due to confinement of the plasma material within a smaller volume by the higher ambient oxygen pressure, hence enhancing the rate of collisional excitation and the corresponding visible emission. A continuous increase in emission with oxygen pressure was observed in the $0 \leq z < 20$ mm region. However, for distances of 20 to 30 mm, the radiated emission increased and reached a maximum at 0.1 mbar above which it fell off. Having previously recognized, that the best quality hexaferrite films are obtained at 30 mm and 0.1 mbar, it can be insinuated that the excited state species provide the necessary surface mobility to promote perpendicularly (c_{\perp}) oriented growth.

It is interesting to examine the nature of the emitting species and effective plasma temperatures along the axis of the plume at 0.1 mbar. Beginning at 2 mm, the main spectral characteristics were similar to those found in vacuum (Fig. 1) i.e., predominant radiation from Ba^+ with less prominent emissions from neutral Ba and Fe. However, at distances further away from the target, this dominance of Ba^+ transitions slowly receded and stronger emissions from Ba and Fe neutrals emerged as a result of collisional recombination processes. Assuming local thermodynamic equilibrium conditions, the effective temperature of the plasma, as estimated from the temporally integrated Ba^+ emission line intensity ratios decreased over the range 1.4–0.8 eV as the contact front of the plume expanded from 2 to 30 mm. The high temperatures (9500 K) of the species incident on the growing film are thought to facilitate film crystallization and oriented growth.

Further insight into the ablation process was gained by recording the temporal evolution of the Ba (553.5 nm), Fe (438.3 nm), and Ba^+ (614.2 nm) emissions at positions 5, 10, and 20 mm from the target, in different oxygen pressures. The delay time, at which peak radiation was attained, yielded straightforwardly the most probable front axial velocity v_z . The results indicated that at small distances from the target surface ($z = 5$ mm), the Ba^+ species outnumbered the Ba and Fe neutral population in agreement with the time integrated data. Moreover, the intense ion emission front was observed in advance of the corresponding neutral front by 10%–20%. Increasing the oxygen pressure up to 0.5 mbar caused an increase in the emission intensities and a minor shift in the corresponding temporal profiles towards greater delay times. It appears, that the dense plasma expands virtually unhindered by the background oxygen at this region. The explanation for the nondependence of the species velocity on the oxygen pressure is to be found on the mass of the ablated products which is large compared to that of the background gas, set in motion by the plume.⁶

Increase in oxygen pressure had a more pronounced influence on the temporal profiles at greater distances from the target. Figure 2 shows the Fe (438.3 nm) time traces at 20 mm. Evidently the emission maximum is increasingly delayed by an increase in oxygen pressure which implies that the plasma expansion is slowed by the higher oxygen pres-

FIG. 2. Temporally resolved emission profiles of Fe recorded 20 mm from the target, in 10^{-5} , 0.1, and 0.5 mbar oxygen.

sures. Moreover, comparable maximum velocities (v_z) were obtained for the emission fronts of all the species ($\sim 8.4 \times 10^5$ cm/s at 0.1 mbar and $\sim 4.6 \times 10^5$ cm/s at 0.5 mbar). A closer inspection of the temporal profiles recorded at 20 mm revealed a fast and slow component, the latter being eminently intensified with oxygen pressure.

At 0.5 mbar the plasma front was cooled to such an extent that a decrease in the peak emission was observed at the location of 20 mm (Fig. 2). It is apparent that a further decrease in the peak emission is expected at the longer distance of 30 mm for the same oxygen pressure. At 0.5 mbar the luminous plume length is smaller than the target-substrate distance of 30 mm and mainly thermalized nonluminous species, transported by diffusion, reach the substrate. The low kinetic energies of the species, together with changes from the stoichiometric arrival cation ratio, are responsible for the presence of misaligned grains and/or foreign phase in the films grown at pressures much higher than 0.1 mbar.¹ Nevertheless, optimum crystalline and morphological properties could be obtained for a target substrate distance of about 30 mm at a pressure of 0.1 mbar, i.e., for a substrate position within the end of the fully expanded plume.

In Fig. 3 are shown 2D images depicting expanding visible Ba ferrite plume in vacuum and 0.1 mbar 1 and 2 μ s after the laser impact. It is clearly shown that the background oxygen pressure confines the plasma slows its expansion and enhances the emission particularly at its expansion front. The bright luminance at the expansion front, is correlated principally with the delayed intense peaks of Fig. 2.

A qualitative picture of the plasma plume dynamics emerges from these spectroscopic results. In vacuum fast "hot" highly ionized material expands rapidly in essentially a free collisionless expansion, strongly forward directed ($v_z \sim 6.6 \times 10^6$ cm/s), leaving behind it, cooler, slower, mainly neutral material. In an oxygen atmosphere, the fast components at the contact front are progressively slowed down re-

FIG. 3. ICCD images of the visible plasma emission recorded 1 and 2 μ s after laser impact upon a $\text{BaFe}_{12}\text{O}_{19}$ target in an oxygen pressure of 10^{-5} (a) and (b) and 0.1 (c) and (d) mbar.

sulting in collisional redistribution of high z directed velocities into x and y directions⁷ producing a more homogeneous plasma with an equilibrated temperature smaller than 1 eV.

IV. CONCLUSIONS

Temporal emission profiles and time resolved ICCD optical images of the plasma clearly demonstrate, how increasing the oxygen pressure confines the plasma, slows its expansion and enhances the emission particularly at its expanding front. It is concluded that the role of oxygen pressure is not only to supply the oxygen constituent to the film but also to slow down the highly energetic species which otherwise will cause damage to the deposited layer.

A Mn–Zn ferrite with a grain size of about 2 μm has been developed for the transformer driven at around 1 MHz. The developed ferrite exhibits considerably lower core losses than a conventional Mn–Zn ferrite with a grain size of about 10 μm at a frequency of 0.5 to 2 MHz. The thin-type transformer using the developed ferrite driven at 1 MHz shows a high efficiency of more than 95% at an output power of 10 to 17 W and a much lower surface temperature rise than the transformer using the conventional ferrite. © 1998 American Institute of Physics. [S0021-8979(98)42211-4]

I. INTRODUCTION

Low-profile transformers are necessary to miniaturize the power supplies because the transformers are one of the largest components of a power converter. Miniaturization of the transformers has been investigated in high frequency driving up to the MHz range. Therefore, the core materials used in the low profile transformer are desired to have low core losses at the MHz range. Thus, we have developed a fine grained Mn–Zn ferrite^{1,2} for high frequency driving at the MHz range. Moreover the low-profile transformer should have the structure, in which uniform flux density in the core and current density in the conductor are achieved, to reduce the core and copper loss. A conductor-embedded-type transformer has been suggested to meet the needs of the transformer design.^{3,4} In this article, we report on the performance of the fine grained Mn–Zn ferrite and a thin-type transformer with the conductor-embedded-type structure using the developed ferrite.

II. EXPERIMENT

Mn–Zn ferrite with a fine grain was prepared by a conventional powder metallurgical process. The raw materials are hydrothermally precipitated ferrite powder and additives, 0.01 wt %SiO₂, 0.021 wt %CaCO₃, 0.038 wt %Ta₂O₅, and 0.034 wt %TiO₂. The composition and the particle size of the hydrothermal ferrite powder are Fe_{2.08}Mn_{0.73}Zn_{0.19}O₄ and about 0.13 μm , respectively. The hydrothermal ferrite powder and the additives were uniformly mixed with a planetary ball mill and calcined at 1173 K in pure nitrogen. The calcined powder was then pressed into a disk shape and sintered at 1348 K for 4 h in the reduced atmosphere of about 30 Pa.

Core losses of the developed ferrite were compared with those of a conventional Mn–Zn ferrite, which is widely used as a core material for the driving frequency at less than 500 kHz. The core losses were measured on the condition of $B_m \times f = 25\,000$ [T \times Hz] at a frequency from 100 kHz to 2 MHz and $B_m = 15$ to 75 mT at 1 MHz, where B_m is a peak

value of the induced flux density and f is driving frequency. Dimensions of the samples are an outer diameter of 8 mm, an inner diameter of 4 mm, and a thickness of 2 mm. The conductor-embedded-type transformers³ were constructed using the developed ferrite and the conventional ferrite. A ratio of the primary and secondary windings is 2:1. These windings were made of a copper foil and separated by a polyimido insulator. Efficiency and a temperature rise of the transformers were measured on a condition of an input voltage of 30 V under a sinusoidal wave at 1 MHz varying the current by changing the load resistance.

III. RESULTS AND DISCUSSION

A. Core loss of fine grained Mn–Zn ferrite

Figure 1 shows the microstructures of the developed fine grained Mn–Zn ferrite and the conventional Mn–Zn ferrite. The grain size of the developed ferrite is about 2 μm , which is much smaller than the 10 μm of the conventional ferrite. Figure 2 shows the frequency dependence of the core losses (P_{cv}) for the developed ferrite and the conventional ferrite. The developed ferrite exhibits low P_{cv} compared with the conventional ferrite at a frequency range from 0.5 to 2 MHz. Especially at 1 MHz, P_{cv} of the fine grained ferrite is about 25% that of the conventional ferrite. Table I shows computationally separated loss components of P_{cv} ,⁵ which are the eddy current loss (P_e), the equivalent dielectric loss (P_d)

FIG. 1. Microstructures of the fine grained ferrite and the conventional ferrite.

FIG. 2. Core losses as a function of frequency for the fine grained ferrite and the conventional ferrite.

due to displacement currents, the hysteresis loss (P_h), and the residual loss (P_r), for the developed ferrite and the conventional ferrite at 1 MHz. P_r of each ferrite occupies a large part of the P_{cv} , the ratio of P_r on P_{cv} in the developed ferrite and the conventional ferrites are 54% and 87%, respectively. P_r of the developed ferrite is about 85% lower than that of the conventional ferrite. P_{cv} of the developed ferrite, therefore, is lower than that of the conventional one. It has been reported that the core losses of ferrites in the MHz range are reduced with a decreasing of the grain size.⁶⁻⁹ Although not understood sufficiently, the cause of this effect is supposed that any magnetic resonance would be suppressed. For example, the suppression of natural resonance can be considered. It is known that the domain of ferrites is subdivided with a decreasing of the grain size.¹⁰ With the decrease of the domain size, the number of domain walls per volume increase; therefore, the amplitude of vibration in each domain wall is reduced in the same B_m . In other words, the switching frequency of the spin inside the domain wall (fs) is reduced. The low P_r of the developed ferrite is presumably caused by the suppression of the natural resonance for the spin inside the domain wall¹¹ at 1 MHz owing to low fs .

In power supplies the input capacity (P_{in}) is an elemental property. P_{in} is expressed by the following equation:¹²

$$P_{in} = 4.44 \times f \times B_m \times N \times I \times A_{ce}, \quad [W], \quad (1)$$

where f is switching frequency, B_m is maximum flux density, N is turn number of windings, I is input current, and A_{ce} is effective core cross sectional area. It is clear from the Eq. (1) that P_{in} is determined by $f \times B_m$ and allowable $f \times B_m$ is limited by the core losses. Figure 3 shows the core losses as a function of B_m for the developed ferrite and the conven-

FIG. 3. Core losses as a function of B_m for the fine grained ferrite and the conventional ferrite.

tional ferrite at 1 MHz. At the same level of the core loss, B_m of the developed ferrite is larger than that of the conventional ferrite. For instance, B_m of the developed ferrite is about 1.6 times larger than that of the conventional ferrite at 400 kW/m³. Therefore, the transformer using the developed ferrite is expected to achieve a higher P_{in} when compared with the transformer using the conventional ferrite in the same transformer configuration. In other words, it is possible to miniaturize the transformer by using the developed ferrite in the same P_{in} because N or A_{ce} can be reduced owing to the large B_m .

B. Performance of conductor-embedded-type transformer using fine grained ferrite

We made a conductor-embedded-type transformer³ using the developed ferrite and the conventional ferrite to confirm the performance of the developed ferrite as a thin-type transformer for a high frequency converter. Figure 4 shows the structure of the transformer. In the conductor-embedded-type transformer, the primary and secondary coils were arranged in the ferrite core and the height of the transformer is only 3 mm. Moreover, minimized flux leakage, uniform flux density, and current density are achieved by having an en-

TABLE I. Each loss component at a frequency of 1 MHz, B_m of 25 mT for the developed ferrite and the conventional ferrite.

Sample	P_{cv}	P_e	P_d	P_h	P_r

closed conductor within the ferrite.^{3,4} Figure 5 shows the output power (P), efficiency (η), and surface temperature rise (ΔT) of the transformers as a function of the output current (I). The transformers exhibit a high η of more than 95% at an output power of 10 to 17 W. High efficiencies are presumably associated with the structural characteristics, as mentioned above. ΔT of each transformer increases with increasing I , because the copper losses increase. The transformer using the developed ferrite shows a high η and a low ΔT as compared with that of the conventional ferrite. A clear difference between the two transformers can be seen in ΔT . ΔT of the transformer using the developed ferrite is about 10 °C lower than that of the conventional ferrite irrespective

of I . The low ΔT is caused by the low core loss of the developed ferrite at 1 MHz. For the safe operation of transformers, ΔT is limited in the transformer design.¹³ In the limited ΔT , the maximum power capacity of the transformer using the developed ferrite is higher than that of the conventional ferrite. For instance, at the same level of ΔT , 30 °C, the power capacity of the transformer using the developed ferrite is 40% larger than that of the conventional ferrite. Therefore, the fine grained ferrite is expected to be useful as the core material for the transformers driven at a high frequency around 1 MHz and the conductor-embedded-type transformer using the fine grained ferrite is effective in realizing the low profile and high-density switching converter.

IV. CONCLUSION

We have developed the fine grained Mn-Zn ferrite with a grain size of 2 μm . The developed ferrite exhibited low core losses as compared with the conventional Mn-Zn ferrite at a frequency range from 0.5 to 2 MHz. Therefore, at the same level of core loss, it is possible for the developed ferrite to drive in a high flux density at a high frequency. The thin-type transformer, the conductor-embedded type, using the developed ferrite shows high efficiencies and low surface temperature rises at the driving frequency of 1 MHz when compared with the transformer using the conventional ferrite. It is concluded that the fine grained Mn-Zn ferrite is suitable for high frequency driving and effective in achieving the transformers with a low profile and high power density.

Active powders of Ni–Zn ferrite were synthesized by soft chemical approaches and were processed with varying concentrations of Bi₂O₃. The sintered products were characterized extensively using a vibrating sample magnetometer, scanning electron microscopy, and resistivity techniques. The loss factor and the permeability have been evaluated. At an optimum concentration of Bi₂O₃ doping the loss factor has been reduced by 20%. The rotational responses are found to be strongly dependent on particle size. © 1998 American Institute of Physics. [S0021-8979(98)19611-1]

I. INTRODUCTION

High electrical resistivity and low magnetic coercivity make Ni–Zn ferrite a technologically important material for applications in the megahertz frequency region.^{1,2} The performance characteristics of these ferrites in this frequency region are being improved by following a variety of synthetic approaches and selective grain and grain-boundary doping.³ The main focus is to reduce the loss factor at the operational frequency and to improve the rotational responses. As the main loss mechanism in the megahertz frequency region is due to an eddy current, efforts are being made to increase the resistivity of this material further so as to considerably reduce the loss. Within the same chemical composition of the material under consideration, the performance characteristics are determined by the microstructural features, viz., size, shape, and orientation of individual particles.³ To tailor these materials, a new concept of microstructural engineering has been evolved in the scientific literature. Recently we have been able to reveal a useful microstructure–magnetic permeability correlation in Ni–Zn ferrite.⁴ It is shown that the initial permeability of this material and the frequency at which the loss factor gives a minimum strongly depend on the microstructural features of this material.

In the present work, we have followed soft chemical approaches to synthesize fine particles of Ni–Zn ferrite (<50 nm) as the conventional ceramic method yielded particles of bigger size (>1 μ m). High resistivity Bi₂O₃ is doped at the grain boundary in different proportions. The choice of Bi₂O₃ is based on the fact that it is nonmagnetic, it has a low melting temperature, and it is a nonferrite forming oxide. The loss factor has been reduced substantially at optimal doping of 2 wt % Bi₂O₃. We have been successful in showing a clear correlation between rotational responses and the microstructure in Ni–Zn ferrite.

II. EXPERIMENT

Active powders of Ni–Zn ferrite, (a representative composition Ni_{0.8}Zn_{0.2}Fe₂O₄) have been synthesized by a soft

chemical method at a temperature as low as 80 °C with a saturation magnetization of 45 emu/g and particle size <50 nm. Details of the synthesis are described elsewhere.⁵ This active powder is divided into five batches and they were mixed with 0, 1, 2, 4, and 6 wt % Bi₂O₃ (the samples are labeled as B0, B1, B2, B4, and B6, respectively). This mixture was mixed with 2 wt % PVA and pressed into toroid and pellet forms. The toroids and pellets were then sintered in air at 1100 °C for 1 h.

The microstructural features of all the samples were obtained using a (Leica–Cambridge 440) scanning electron microscope (SEM). The sintered pellets were fractured to expose the inside portion and mounted onto a specimen mounting stub. The samples were coated by a thin layer of gold to prevent charging of the specimen. The porosity of the material is calculated from the density of the material and the theoretical density. For the theoretical density calculation it is assumed that the doped Bi₂O₃ exists as such. The initial permeability (μ_i) and the loss factor ($\tan \delta \mu_i$) of all the toroids were evaluated using a Q meter (HP 4192) in the frequency range 1–40 MHz. The two probe dc resistivity of all the samples was measured using an Impedance bridge (General Radio 1608A). Both surfaces of the pellets were coated with conducting silver paste before being sandwiched between the two electrodes of the sample holder for improved electrical contact. The Curie temperature (T_c) and the saturation magnetization at room temperature for all the samples were measured using a vibrating sample magnetometer (EG&G PAR 4500). The room temperature saturation magnetization was obtained from the hysteresis loop measurement in a field range of ± 15 kOe. The (T_c) was obtained from the temperature dependence of magnetization.

III. RESULTS AND DISCUSSION

Figures 1(a) and (b) show the scanning electron micrographs of samples B0 and B2, respectively. It is clearly seen from the micrographs that the undoped sample, B0, has an average particle size of ~ 300 nm. With 2 wt % Bi₂O₃ doping the grains have grown substantially to ~ 3 μ m. The particle sizes obtained from the scanning electron micrographs of all the samples (B0, B1, B2, B4, and B6) are given in Table I. It

FIG. 1. The SEM of (a) B0 and (b) B2. The micrograph shown in (c) is an enlarged version of (b).

Bi_2O_3 at the grain boundary. This is clearly shown in Fig. 1(c) which is an enlarged micrograph of Fig. 1(b).

Figure 2 shows the temperature dependence of the magnetization for samples B0, B1, and B6. It may be seen from Fig. 2 that the $T_c \sim 485^\circ\text{C}$ for all the samples. The (T_c) for the undoped as well as for the Bi_2O_3 doped samples is the same, indicating that the doped Bi_2O_3 has not altered the cation distribution or the chemical composition of the ferrite phase. Hence it is concluded from the magnetic measurements and SEM micrographs that the doped Bi_2O_3 has been trapped in the grain boundaries. The inset in Fig. 2 shows the hysteresis loop for B0 and B6. The magnetization at 15 kOe is less for B6 compared to that of B0. This is due to the presence of nonmagnetic Bi_2O_3 along with the ferrite phase.

In Table I, the room temperature electrical resistivity, the porosity, and the initial permeability (μ_i) measured at 5 MHz of all the samples are given along with the particle size. The resistivity of B0 is of the order of $10^6 \Omega \text{ cm}$. For Bi_2O_3 doped samples the resistivity is considerably increased by two orders of magnitude ($\sim 10^8 \Omega \text{ cm}$). It has been shown that the resistivity of Ni-Zn is comprised of grain and grain-boundary resistivities.⁶ Hence the increase in resistivity for the doped samples is assigned to the increase in the intergranular resistivity due to the presence of high resistivity⁷ Bi_2O_3 at the grain boundary. The porosity of the samples decreased with an increase in the % of Bi_2O_3 of doping. This is because of the filling of the voids by the doped Bi_2O_3 .

The initial permeability of the undoped sample is ~ 37 . It is known that the permeability of a polycrystalline sample is described as the superposition of two magnetization mechanisms, i.e., spin rotation and domain-wall motion^{8,9} so that

$$\mu_i = 1 + \chi_{\text{spin}} + \chi_{\text{dw}},$$

where χ_{spin} and χ_{dw} are magnetic susceptibility due to spin rotation and domain-wall motion, respectively. For single domain particles the contribution to permeability from domain-wall motion is absent. B0 possesses submicron par-

FIG. 2. The temperature variation of magnetization of $\text{Ni}_{0.8}\text{Zn}_{0.2}\text{Fe}_2\text{O}_4$ with different amounts of Bi_2O_3 doping. Data for the undoped sample are not shown below 390 K for clarity. Inset: Hysteresis loops for (a) undoped and (b) 6 wt % Bi_2O_3 doping.

is clearly seen from Table I that the particle size remains unchanged for different degrees of Bi_2O_3 . For the Bi_2O_3 doped samples, the presence of an additional phase is seen at the grain boundaries and is assigned to the presence of doped

TABLE I. Average particle size, room temperature electrical resistivity, porosity, and initial permeability of $\text{Ni}_{0.8}\text{Zn}_{0.2}\text{Fe}_2\text{O}_4$ with different Bi_2O_3 doping levels.

Sample	B0	B1	B2	B4	B6
Percentage of Bi_2O_3 doping	0	1	2	4	6
Average particle size	~ 300 nm	~ 3 μm	~ 3 μm	~ 3 μm	~ 3 μm
Resistivity Ω cm	3.5×10^6	6.7×10^8	5.2×10^8	4×10^8	3.5×10^8
Porosity (%)	13	9.7	6.5	5.8	5.4
Initial permeability μ_i 5 MHz	37	75	70	64	48

ticles which are single domain particles. For B1 the permeability is ~ 75 and the particle size is ~ 3 μm . van der Zaag *et al.*¹⁰ have earlier shown that particles with sizes ≥ 3 μm are multidomain. Hence the contribution from the domain-wall motion enhances the initial permeability of B1. For Bi_2O_3 doped samples the particle size remains unchanged; however the permeability decreases as the % of Bi_2O_3 increases. This is likely to be due to the incorporation of excess nonmagnetic material between the grains.

Figure 3 shows the loss factor V_s frequency curves of all the samples. The loss factor has been substantially reduced by 20% up to 2 wt % Bi_2O_3 doping compared to the undoped sample. A further increase in the Bi_2O_3 concentration increases the loss factor. The frequency at which the loss factor gave a minimum (f_{lossmin}) shifted to low frequency for the Bi_2O_3 doped samples. For the undoped sample $f_{\text{lossmin}} \sim 25$ MHz whereas for the Bi_2O_3 doped samples $f_{\text{lossmin}} \sim 5$ MHz. This is due to the increase in grain size for the doped samples. Although the porosity of the samples is progressively decreasing, f_{lossmin} remains unchanged for the doped samples. The interesting observation that (i) the grains grow substantially with Bi_2O_3 doping, (ii) the grain size of the

sintered ferrites, however, remains same for different degrees of Bi_2O_3 doping, (iii) f_{lossmin} shifts from ~ 25 to ~ 5 MHz on doping, (iv) f_{lossmin} remains unchanged from B1 to B6, and (v) the initial permeability is increased substantially for B1 compared to B0, suggesting that the rotational responses are particle size dependent.

IV. CONCLUSION

Fine particles of Ni-Zn ferrite were synthesized and processed with varying concentrations of Bi_2O_3 and the doped Bi_2O_3 is distributed in the grain boundaries as evidenced by scanning electron micrographs and the (T_c) measurements. The resistivity of the material is increased considerably due to the presence of high resistivity Bi_2O_3 at the grain boundaries. The Bi_2O_3 doping has increased the particle size of the material considerably. It is observed that the rotational responses are particle size dependent rather than porosity. With optimal doping of 2 wt % Bi_2O_3 we could reduce the loss factor considerably (20% reduction). We have developed a low power-loss material and demonstrated the dependence of rotational response to particle size in Ni-Zn ferrite.

We have produced MnZn ferrites via high-energy ball milling (HEBM) of elemental oxides MnO, ZnO, and Fe₂O₃. X-ray diffraction (XRD) indicates a pure phase spinel forms after 21 h of HEBM. Extended x-ray absorption fine structure (EXAFS) analysis shows a nonequilibrium cation distribution, with an unusually high population of Zn cations on the octahedral sublattice. We then used EXAFS modeling to study cation site occupancy in an equilibrium MnZn-ferrite standard subjected to HEBM. We found that HEBM produces an increased preference for octahedral-site occupation among all cations for milling durations up to 300 min. After an initial improvement in magnetic properties, the magnetization diminishes steadily throughout this interval. With further increases in milling duration these structural and magnetic trends reverse, possibly due to annealing effects evidenced by XRD. © 1998 American Institute of Physics. [S0021-8979(98)42311-9]

The technique of high-energy ball milling (HEBM) has been the subject of great interest in recent years due to its promise for producing improved and/or novel materials through mechanical attrition or alloying.¹ Spinel ferrites are particularly attractive candidates for such processing studies due to their importance both in solid-state microwave devices and in soft magnet applications where loss minimization is critical.² Despite these motivations, there have been few investigations of ferrite production via ball milling.

In an early work, Lefelshtel *et al.*³ attempted to alloy ZnO and Fe₂O₃ in a ball mill, achieving partial conversion to ZnFe₂O₄ according to x-ray diffraction (XRD). Peaks associated with the elemental oxides were still dominant. More recently, Kosmac and Courtney⁴ subjected ZnO and Fe₂O₃ to HEBM and found that Zn ferrite became the dominant phase after 2.5 h. However, no trace of the spinel phase was seen by XRD after another 2.5 h milling. Similar results were achieved in the alloying of Ni ferrite from NiO and Fe₂O₃. Subsequently, Jovalekic *et al.*⁵ combined NiO and Fe₂O₃ and attributed all peaks in the XRD pattern to the spinel phase after milling 35 h, with little change in the XRD pattern upon subsequent milling. In a different application of ball milling, Hamdeh *et al.*⁶ subjected partially inverted ZnFe₂O₄ to HEBM for 10 h, increasing the inversion parameter and the magnetization.

In this article, we report the formation of MnZn ferrite from HEBM of MnO, ZnO, and Fe₂O₃. We find these milled ferrites have low temperature magnetization and coercivity equal to those processed via traditional ceramic processing techniques. We provide structural analysis of the product through both XRD and extended x-ray absorption fine structure (EXAFS) studies. Multiple scattering EXAFS analysis⁷ shows the milled ferrites to have a higher inversion param-

eter than a standard ferrite of similar stoichiometry, with an unusually high population of Zn ions on the octahedral sublattice.

Modification of the MnZn ferrite standard by HEBM was also performed. EXAFS analysis reveals that HEBM increases octahedral-site occupation among all cations for times up to 5 h. Superconducting quantum interference device (SQUID) magnetometry indicates improved magnetic properties in samples milled for short durations, followed by diminished magnetization with increased milling. With milling durations greater than 5 h the structural and magnetic trends reverse, possibly due to annealing effects.

Processing of MnZn ferrite was accomplished by combining MnO, ZnO, and Fe₂O₃, totaling 5 g, with the molar ratio 1:1:2 in the steel vial of the SPEX 8000 high-energy shaker mill. The vial was loaded with two stainless steel 8 g balls and two 1 g balls in air and shaken at about 1200 Hz. In order to maintain an equal ball:powder mass ratio for all samples, the vial was cleaned and reloaded with 5 g of new material for each milling trial.

Modification of a standard MnZn ferrite, prepared by traditional fire-and-grinding techniques, was achieved by subjecting 2.6 g samples of the standard to HEBM for periods ranging from 0.5 to 9 h.

Samples were characterized for their structural properties using XRD and EXAFS, and for their magnetic properties using SQUID magnetometry. θ - 2θ XRD scans were performed using a Philips XRG 3100 x-ray generator and Cu $K\alpha$ radiation. Refinement analysis leading to calculation of the lattice parameter was performed using the Philips APD™ software package.

EXAFS data were collected using beamlines X23B and X23A2 of the National Synchrotron Light Source at Brookhaven National Laboratory. The beamlines use double-crystal, fixed-exit monochromators, with Si (111) crystals in X23B and Si (311) crystals in X23A2. All spectra reported here were collected using the transmission technique.⁸ The storage ring current and energy at the time of data collection

^{a)}Electronic mail: dfatemi@anvil.nrl.navy.mil

were 200–350 mA and 2.5 GeV, respectively. Samples consisted of powders spread uniformly onto adhesive tape with several layers of powdered tape constituting a single sample. The number of layers was chosen empirically to provide nearly one absorption length at the absorption edge being measured.

EXAFS analysis followed established procedures⁹ leading to the Fourier transformation of EXAFS data to radial coordinate space (Å). Quantitative analysis of the cation distribution followed the approach previously employed by Harris *et al.*⁷ which included the least-squares fitting of multiple-scattering simulated XAFS data generated using the codes of Rehr *et al.*¹⁰

Portions of XRD patterns for the starting material, the sample ball-milled 21 h, and a standard $\text{Mn}_{0.5}\text{Zn}_{0.5}\text{Fe}_2\text{O}_4$, prepared by conventional ceramic techniques, are shown in Fig. 1. The calculated lattice parameter for the standard is 8.431 Å.

The XRD scan for the starting material contains peaks characteristic of MnO, ZnO, and Fe_2O_3 phases. However, after 21 h milling, peaks only attributable to the MnZn ferrite phase are observed, with even the most intense peaks in the starting material's data (see, for example, $2\theta = 33.5^\circ$, 50° , and 54.5°) no longer visible. XRD features for the milled samples have broadened and have reduced amplitudes coinciding to the formation of fine-grained strained particles which are characteristic of the HEBM technique. The calculated lattice parameters for the 21 h and 40 h milled ferrites are 8.422 and 8.429 Å, respectively.

Hysteresis loops, i.e., M vs H curves, collected using a SQUID magnetometer at 10 K reveal that the MnZn ferrite processed through ball milling is equal in magnetization and coercivity to that of the standard. These data are collected at low temperatures to overcome the superparamagnetic contribution of the milled sample.

Fourier transformed (FT) EXAFS data collected from Fe, Mn, and Zn K absorption are shown in Fig. 2. Transforms for the 40 h ball-milled sample are compared with similar data collected from the standard. The positions of the Fourier peaks typically correspond to bond distances (uncorrected for electron phase shifts) between the absorber and the backscatterers, while the amplitudes arise predominantly from the coordination and the atomic order of atom shells at that distance. The Fourier peaks seen in Fig. 2 have been assigned to atom pair correlations within the ferrite unit cell.¹¹ The appearance of Fourier peaks of significant amplitude over the full range of r space indicates that the ferrite forms with both short-range and long-range ordering.

In Fig. 2 the data sets in each panel are plotted on different y-axis scales. The reason for this is the reduced Fourier peak amplitudes characteristic of the large atomic disorder created by the ballistic nature of HEBM processing. It is interesting to note that the near neighbor oxygen peaks do not experience large disorder, whereas the cation–cation and next near neighbor oxygen correlations are strongly affected. We postulate that the strong ionic character of the metal–oxygen bond maintains the structural integrity of the polyhedra subunits and defines the cleavage planes to occur between polyhedra joined at edges and corners.

FIG. 1. Partial θ – 2θ x-ray diffraction scans illustrating ferrite formation from the ball milling of elemental oxides (radiation used was $\text{Cu } K_\alpha$).

The chief feature in the Fourier transform which signifies tetrahedral-site (A-site) occupancy for the absorber is the peak near 3.1 Å [denoted A on panel (a)]. The peak's amplitude predominantly arises from the scattering of 12 B-site cations and 12 anions centered near 3.48 Å. The octahedral-site (B-site) absorber is similarly fingerprinted by a peak near 2.6 Å [denoted B on panel (a)]. The amplitude arises solely from the scattering of six B-site cations and six anions centered near 2.97 Å (both Fourier peaks are shifted to small r due to electron phase shifts). The amplitudes of these peaks reflect qualitatively the distribution of absorbing cations on the A and B sites.

In comparing the B:A peak ratios of the sample milled 40 h to the standard, one infers that the milled sample possesses a higher fraction of Fe and Mn cations on the A sublattice, while an unusually high population of Zn cations resides on the B sublattice. Numerous studies have established that Fe and Mn cations may occupy both A- and B- sites depending upon the type and amount of other cations present. Zn cations, in contrast, do not typically occupy B sites. However, recent work by Hamdeh *et al.*⁶ suggests that ball milling of partially inverted Zn ferrite aerogels increases B-site filling by Zn cations.

Stabilization of nonequilibrium cation distributions was subsequently investigated through HEBM of the MnZn ferrite standard. FT Mn EXAFS data for the standard and samples ball milled between 45 and 540 m are shown in Fig. 3. All of the features to be discussed in this report are also seen in Fe and Zn EXAFS.

The inset in Fig. 3 shows the ratio of the amplitudes of the B and A peaks as a function of milling time. Up to 5 h, all cations show increased B-site occupation with milling

FIG. 2. Fourier transformed (a) Fe, (b) Mn, and (c) Zn EXAFS data from MnZn ferrite formed after 40 h of milling and from the standard (k weighting for all data is k^3 with k ranges of (a) 2.85–13.4, (b) 3.1–11.7, and (c) 2.5–12.6 \AA^{-1}).

duration. However, this trend reverses after 5 h for all cations, with the distribution returning to near equilibrium for Fe and Mn cations after 9 h milling.

Particle size analysis was performed using the Scherrer method. Though the technique is not definitive as it ignores line broadening in the XRD pattern due to strain, it is interesting that this analysis indicates a trend of decreasing particle size for durations between 0.75 and 5 h, with the thickness dropping from 16.6 to 11.2 nm. This trend then reverses, yielding a crystallite diameter of 13.6 nm after 9 h milling. The direct correlation between particle size measurements and B-site occupation by cations suggests that the altered site distribution may be due to a modified surface structure, possibly arising from oxidation of cations near the surface. This is consistent with recently reported models by Chen *et al.*¹² and van der Zaag *et al.*¹³ Charge conservation is provided by the creation of additional vacancies on the A sublattice, as seen by the reduced A peak in the FT EXAFS data.

FIG. 3. Fourier transformed Mn EXAFS data for milled samples and starting material. Data are k^3 weighted with k range of 3–11.7 \AA^{-1} .

SQUID magnetometry shows that after 0.5 h milling, samples possess increased low-temperature saturation magnetization and reduced anisotropy fields. These improvements may be due to enhanced imbalance between sublattice moments resulting from segregation of Mn^{III} ions to the B sublattice. However, upon further milling, magnetization diminishes rapidly until after 5 h, when improvement again occurs, yielding a magnetization in the sample milled 9 h that is similar to the standard. XRD measurements indicate that some dissociation occurs and increases with milling duration, peaking near 5 h, after which this trend reverses. This suggests that the reduced magnetization may arise from the presence of secondary phases.

The effect of intragranular domain walls in MgMnZn-ferrite

The effect of grain size, D , on the intragranular domain state and initial permeability, μ_i , of polycrystalline MgMnZn ferrites has been investigated. The intragranular domain state is found to change from mono- to two domain at $D=2.9\pm0.2\ \mu\text{m}$. Despite this change, μ_i follows a continuous dependence on D , which can be described by the nonmagnetic grain boundary model. The results show that in spinel ferrites with an anisotropy of $72\ \text{J/m}^3$, μ_i is still due to rotation of magnetization. © 1998 American Institute of Physics. [S0021-8979(98)19711-6]

I. INTRODUCTION

It is well known that the initial permeability, μ_i , of polycrystalline soft ferrites depends on grain size, D . The traditional domain wall size (DWS) model by Globus and co-workers considers this grain size dependence to be due to bulging of a domain wall spanning each ferrite grain.¹ Recently, a different model has been proposed.²⁻⁴ In this nonmagnetic grain boundary (NMGB) model, μ_i of polycrystalline ferrites is considered to be influenced by a "non"-magnetic grain boundary. In this model rotation of magnetization is the dominant mechanism for μ_i .

We have shown by neutron depolarization⁵ that in MnZn ferrites with grain size $D<3.8\ \mu\text{m}$, the grains are monodomain and intragranular domain walls are absent.^{6,7} (The occurrence of a monodomain state in these fine-grained MnZn ferrites has been confirmed by magnetic force microscopy.⁸) Since intragranular domain walls are absent at $D<3.8\ \mu\text{m}$, μ_i must be due to rotation of magnetization in these MnZn ferrites. Moreover, up to $D=16\ \mu\text{m}$, the D dependence of μ_i could be described by the NMGB model, without a discontinuity at the transition from the mono- to two-domain state.⁷ This also shows for two-domain MnZn ferrites, which contain an intragranular domain wall, that μ_i is due to rotation. The MnZn ferrites considered thus far have a low anisotropy, K , of $32\ \text{J/m}^3$.⁷ One might wonder to which extent the results obtained apply to ferrites with a higher anisotropy. For this purpose the intragranular domain state as well as μ_i of a series of MgMnZn ferrites with constant composition but varying grain size were studied.

II. EXPERIMENTAL PROCEDURES

Ferrites with composition $\text{Mg}_{0.8}\text{Zn}_{0.2}\text{Mn}_{0.1}\text{Fe}_{1.85}\text{O}_{3.925}$ were prepared by conventional ceramic processing. MgMnZn ferrites of this composition have a Curie temperature, T_C , of $220\ ^\circ\text{C}$ and spontaneous magnetization, $\mu_0 M_s$, of $0.32\pm0.01\ \text{T}$ at $20\ ^\circ\text{C}$. By using different milling proce-

dures and adjusting the sinter temperature between 1100 and $1350\ ^\circ\text{C}$, polycrystalline ferrites with a grain size between 0.5 and $8.0\ \mu\text{m}$ were prepared. The mean linear intercept, D , is taken as a measure of the grain size, because it gives an unequivocal definition of grain size independent of the grain shape. D was determined from micrographs, depending on the grain size, either taken by a scanning electron microscope (Philips, SEM 515) or an optical microscope. Sample porosities varied between 2% and 10% . The magnetic domain size in the thermally demagnetized state was determined at room temperature by neutron depolarization.⁵ The initial permeability, μ_i , was determined between -50 and $250\ ^\circ\text{C}$, at a frequency of $10\ \text{kHz}$ and an induction level $B\approx0.04\ \text{mT}$.

III. RESULTS AND DISCUSSION

Figure 1(a) shows a SEM micrograph of the finest-grained MgMnZn ferrite used in this study with $D=0.51\pm0.05\ \mu\text{m}$. Figure 1(b) shows an optical micrograph of the coarsest-grained ferrite in this study with $D=8.0\pm0.8\ \mu\text{m}$.

Figure 2 gives the results of a neutron depolarization (ND) study at zero magnetic field of the domain size, Δ , versus the grain size, D , for $\text{Mg}_{0.8}\text{Zn}_{0.2}\text{Mn}_{0.1}\text{Fe}_{1.85}\text{O}_{3.925}$. It is important to note that ND determines the average domain size *within the bulk* of a magnetic material. As neutrons traverse the grains in a bulk material on random chords, Δ determined by ND also corresponds to a mean linear intercept value. Figure 2 shows similarly to the observations in other ferrites,^{6,7,9} that at low D values the domain size is equal to the grain size as can be seen by comparison to the solid line for which $\Delta/D=1$. At $D>2.9\ \mu\text{m}$ the data points follow the dashed line. This line corresponds to the ratio $\Delta/D=0.63$ calculated for the two-domain state⁶ and confirmed in previous experiments on MnZn ferrite^{7,8} and NiZn ferrite.⁹ Hence, for $D>2.9\ \mu\text{m}$ a domain wall appears to be present in these MgMnZn ferrites. This difference in intragranular domain state is reflected in the MHz dissipation, as has been demonstrated and discussed in more detail previously.⁹ Figure 3 displays the loss factor $\tan\delta\mu$ at $5\ \text{MHz}$ vs D for the MgMnZn ferrites. A reduction of the loss

FIG. 1. Micrographs of the microstructure of two representative MgMnZn ferrites: (a) the finest-grained sample, grain size $D = 0.51 \pm 0.05 \mu\text{m}$, (b) the coarsest-grained sample, $D = 8.0 \pm 0.8 \mu\text{m}$.

factor at the grain size at which the MgMnZn ferrites become monodomain is observed.¹⁰

Theoretically with decreasing grain size a transition from a two- to a monodomain state is expected for an *isolated* particle, because the domain wall energy scales with the domain wall area as $\propto D^2$, whereas the magnetostatic energy decreases more rapidly with D^3 .¹¹ A complication in the case discussed here is that the situation of an isolated

FIG. 2. The domain size Δ as a function of grain size D for $\text{Mg}_{0.8}\text{Zn}_{0.2}\text{Mn}_{0.1}\text{Fe}_{1.85}\text{O}_{3.925}$. The solid line corresponds to $\Delta/D = 1$, the ratio corresponding to monodomain grains; the dashed line corresponds to $\Delta/D = 0.63$, the ratio corresponding to grains in the two-domain state.

FIG. 3. The loss angle $\tan(\delta)/\mu_i$ at 5 MHz vs grain size for the same MgMnZn ferrite composition.

particle is not met in densely sintered ferrites. Hence, in the calculation of the critical grain size, D_C , at which this transition occurs, the reduction of the magnetostatic energy by the soft-magnetic environment has to be taken into account. In a first approximation,⁹ this can be done by using the isotropic permeability correction proposed earlier for the calculation of D_C (mean intercept value).⁷ Applying this correction to the rigorous, analytical expressions derived by Brown¹² for the upper and lower grain size limits at which an isolated particle becomes monodomain yields:

$$D_{C_{\text{lower}}} = 3.6 \sqrt{\frac{A \frac{2}{3} \mu_{ic}}{\frac{1}{2} \mu_0 M_S^2}} \quad (1)$$

$$D_{C_{\text{upper}}} = 28 \sqrt{\frac{A \frac{2}{3} \mu_{ic}}{\frac{1}{2} \mu_0 M_S^2}} \sqrt{\pi + \frac{K \frac{2}{3} \mu_{ic}}{\frac{1}{2} \mu_0 M_S^2}} \quad (2)$$

with A the exchange constant and μ_{ic} the initial permeability at D_C . Using the numerical values for the MgMnZn ferrite studied here: $A = 3.4 \times 10^{-12} \text{ J/m}$, $\mu_{ic} \approx 150$ (see below), $K \approx 72 \text{ J/m}^3$ and $\mu_0 M_S = 0.32 \text{ T}$ yields $0.32 \mu\text{m}$ as a lower limit and $4.7 \mu\text{m}$ as an upper limit for D_C . In view of the approximations made to account for the soft-magnetic environment, the experimentally found $D_C = 2.9 \pm 0.2 \mu\text{m}$ seems reasonable. Micromagnetic theory is being developed which will deal more accurately with the soft-magnetic environment and interparticle interactions.¹³

For $D < 2.9 \mu\text{m}$ intragranular domain walls are absent. Thus in this range the domain wall size (DWS) model¹ cannot hold. It is therefore of interest to investigate the μ_i of these MgMnZn ferrites in this range and just above D_C , where an intragranular domain wall is present. The results of such a study are presented in Fig. 4. Figure 4 gives μ_i at room temperature versus D for the same MgMnZn ferrite composition for which Δ has been determined. The μ_i data were corrected for variations in porosity, p , using the expression²:

$$\mu_i^{\text{corr}} = \mu_i \frac{1 + p/2}{1 - p}. \quad (3)$$

FIG. 4. The initial permeability $\mu_i(\text{eff})$ vs grain size. The curve traced through the data is a fit to the nonmagnetic grain boundary model for μ_i .

The curve in Fig. 4 is a least-squares fit to the NMGB model²⁻⁴:

$$\mu_i(\text{eff}) = \frac{\mu_i D}{\mu_i \delta + D} \quad (4)$$

in which μ_i is the bulk intrinsic initial permeability and δ the nonmagnetic grain boundary thickness. The best fit given in Fig. 4, was obtained with $\mu_i = 329 \pm 31$ and $\delta = 9.4 \pm 0.7$ nm. For $D > 6 \mu\text{m}$, the fit to the NMGB model deviates from the data. Further analysis showed that this is due to *intragranular* porosity, which only occurs in samples with $D > 6 \mu\text{m}$ [compare Figs. 1(a) and 1(b)]. This is the result of the higher sinter temperature (1350 °C) used. Due to increased grain growth at these temperatures, pores can no longer follow the moving grain boundaries during the sintering. Consequently, they become locked within the grains.¹⁴ The interesting aspect of Fig. 4 is that while intragranular domain walls are present at $D > 2.9 \mu\text{m}$ no extra contribution to μ_i is observed. The NMGB model can describe the D dependence of μ_i both in the mono- and two-domain regime. This also implies that in these MgMnZn ferrites the initial permeability is of rotational origin. A similar conclusion has been derived for low anisotropy ($K = 32 \text{ J/m}^3$) MnZn ferrites.⁷ Apparently, at the higher K of this MgMnZn ferrite ($K \approx 72 \text{ J/m}^3$), the initial permeability is of rotational origin also when intragranular domain walls are present within the grains.

Finally, we investigated the effect of temperature on the values found for δ . The results are given in Fig. 5 and were obtained from fits of Eq. (1) of μ_i vs D at various temperatures. Only data for which $D < 6 \mu\text{m}$ were used to avoid the problem of intragranular porosity mentioned above. Interestingly, in the case of MgMnZn ferrite, δ is found to be temperature dependent. This shows that δ cannot be considered nonmagnetic, and is better considered a "hard" magnetic

FIG. 5. The width of the nonmagnetic grain boundary δ vs temperature T for $\text{Mg}_{0.8}\text{Zn}_{0.2}\text{Mo}_{0.1}\text{Fe}_{1.85}\text{O}_{3.925}$. The term δ was determined from fits as shown in Fig. 4. Note that δ depends on T .

grain boundary,⁷ i.e., having a high anisotropy due to spin canting as found for ultrafine ferrite particles.¹⁵

IV. CONCLUSION

We have shown by neutron depolarization that the transition from the mono- to two-domain state occurs at $D = 2.9 \pm 0.2 \mu\text{m}$ in polycrystalline $\text{Mg}_{0.8}\text{Zn}_{0.2}\text{Mn}_{0.1}\text{Fe}_{1.85}\text{O}_{3.925}$. Despite this change in intragranular domain state the NMGB model describes the grain size dependence of the initial permeability, μ_i , well for these ferrites both below and above D_C . This shows that also for ferrites with an anisotropy constant $K = 72 \text{ J/m}^3$ the initial permeability is rotational in origin.

Line width of manganese–zinc ferrite polycrystals with oxygen partial pressure

Soon Cheon Byeon^{a)} and Kug Sun Hong

School of Materials Science & Engineering, College of Engineering, Seoul National University, Seoul 151-742, Korea

In-Tae Kim

Division of Ceramics, Korea Institute of Science and Technology, P.O. Box 131, Cheongryang, Seoul, Korea

A systematic variation in line width at X band (9.78 GHz) with oxygen partial pressure was observed in $\text{Mn}_{0.47}\text{Zn}_{0.47}\text{Fe}_{2.06}\text{O}_4$ polycrystalline samples. The linewidth of the samples increased from 105 to 188 Oe with decreasing atmospheric parameters from 8.4 to 6.4. It was found that contribution of anisotropy and porosity to the linewidth was small compared to the variation in linewidth with oxygen partial pressure. Estimation of the Fe^{2+} concentration of samples by measuring their thermoelectric power revealed that an increase in the concentration from 1.88 to 2.44 wt % was accompanied by decreasing oxygen partial pressure. As the resistivity of grain does not vary with oxygen partial pressure, the contribution of eddy current will be the same irrespective of the oxygen partial pressure. Therefore, the systematic increase in linewidth observed in our present study was attributed to the increase in Fe^{2+} concentration with decreasing oxygen partial pressure. © 1998 American Institute of Physics. [S0021-8979(98)49011-X]

I. INTRODUCTION

Iron-excess manganese–zinc ferrites are widely used in high frequency circuit components such as transformers, noise filters, and magnetic recording heads because both of their electrical resistivities and initial permeabilities are much higher than those of metals at high frequencies (up to 200 MHz). Recently, applications are being extended to include components being used to shield the electromagnetic interference (EMI).^{1,2}

The ferromagnetic resonance (FMR) of ferrites is important to investigate their magnetic properties at high frequency because the resonance originates from the interaction between spin and electromagnetic waves. For instance, the loss of ferrites at microwave frequency largely depends on their line width of FMR. The broader the line width, the more lossy the sample is due to higher dispersion.

Recently, a lot of research has been focused on microwave applications of yttrium iron garnet (YIG) because it has very low loss. In order to reduce the cost, polycrystalline YIG, instead of single crystals, is preferred. In the case of polycrystalline ferrites, it is known that anisotropy as well as porosity contribute to the line broadening of FMR.³ These contributions can be estimated quantitatively. However, there are contributions that can hardly be quantified. One of those is the eddy current loss which represents the conduction of electrons in response to the magnetic field of electromagnetic waves.^{4,5} Since the conduction mechanism of ferrites is known to be a small polaron hopping of electrons between Fe^{2+} and Fe^{3+} ions, the Fe^{2+} concentration should be measured in order to quantify the contribution of eddy current loss. In the case of YIG, however, this is very diffi-

cult because the Fe^{2+} concentration is very low. (As a matter of fact this is the reason that YIG has very low loss.)

Manganese–zinc ferrite has interesting features. Its crystal structure is mixed spinel and it has high Fe^{2+} concentration in octahedral sites. Furthermore, its Fe^{2+} concentration can be easily manipulated by varying oxygen partial pressure during heat treatment. Therefore, the objective of our present study is to investigate the effects of Fe^{2+} concentration of manganese–zinc ferrites on their line width of FMR.

II. EXPERIMENTAL PROCEDURE

Manganese–zinc ferrite of the composition $\text{Mn}_{0.47}\text{Zn}_{0.47}\text{Fe}_{2.06}\text{O}_4$ was prepared using the conventional mixed oxide method. Experimental details were described elsewhere.⁶ The specimens were sintered at 1350 °C for 5 h in an air atmosphere. During cooling, the oxygen partial pressure was controlled using the following equation which was suggested by Morineau and Paulus,⁷

$$\log P_{\text{O}_2} = a - \frac{14540}{T(K)}, \quad (1)$$

where a is atmospheric parameter which represents an oxidation potential. In our present study, the atmospheric parameter was kept constant during the cooling process. In more detail, manganese–zinc ferrite samples with $a = 6.44, 7.07, 7.56, 7.96$, and 8.44 were prepared in order to investigate the effect of oxidation on their line width.

Electrical resistivity was measured at room temperature using impedance spectroscopy. Impedance was measured in the frequency range of 100 Hz to 40 MHz using an impedance/gain phase analyzer (Hewlett Packard, Model HP 4194A). Thermoelectric power was measured at room tem-

FIG. 1. Ferromagnetic resonance spectra of manganese-zinc ferrite samples with various oxygen partial pressures.

perature using the dc method. From these data, the Fe^{2+} concentration was calculated. Please refer to our previous work for details.⁶

Porosity was calculated from the bulk density of the sample which was determined by Arkimedes' method.

Ferromagnetic resonance (FMR) spectra were recorded at 300 K using an X-band (9.78 GHz) spectrometer (Bruker, Model ER 301). Samples were cut and polished to a thin plate with a dimension of $0.5 \text{ mm} \times 0.5 \text{ mm} \times 0.01 \text{ mm}$ and were placed at the center of a cavity oscillating in the rectangular TE_{102} mode. The sample can be rotated on a dielectric post inserted through the wall of the cavity. A conventional field modulation technique was used.

III. RESULTS

Figure 1 shows FMR spectra of manganese-zinc ferrite samples measured at 9.78 GHz. The dc magnetic field was applied perpendicular to the thin plate. The spectra were recorded as a first derivative of the absorption. An increase in resonance field and intensity were observed with increasing oxygen partial pressure. The g values were calculated from the resonance field in different orientations with respect to

FIG. 2. Linewidth as a function of oxygen partial pressure.

the applied field. The g values decreased from 1.95 to 1.90 with increasing atmospheric parameter. Yager *et al.* reported that the g values of a stoichiometric manganese-zinc ferrite is 2.05.^{8,9} In this experiment, the g values are slightly smaller than that of the stoichiometric manganese-zinc ferrite as the composition is iron-excess manganese-zinc ferrite. Yager *et al.* reported that iron-excess ferrites give slightly reduced g values.⁴

It is also noteworthy that there are many subsidiary resonances at a lower field besides the main resonance. These resonances seem to be standing magnetostatic modes.

Figure 2 shows the linewidth as a function of the oxygen partial pressure used in the cooling process. Here the absolute value of the linewidth was of the order of 10^2 Oe and the variation in the linewidth was about 80 Oe. The linewidth decreased almost linearly with increasing oxygen partial pressure.

Table I summarizes the Fe^{2+} ion concentration, resistivity of the grain and the grain boundary, and saturated magnetization ($4\pi M_s$) of the manganese-zinc ferrite samples reported in our previous work.^{6,10} Porosity of the samples is also listed in Table I.

IV. DISCUSSION

A. Quantitative estimation of change in linewidth with Fe^{2+} concentration

As mentioned previously, the linewidth of the FMR of polycrystalline ferrites is a sum of various contributions of

TABLE I. Oxygen partial pressure dependence of grain boundary and grain resistivity, saturation magnetization, and porosity.

Atmospheric parameter (a)	6.44	7.07	7.56	7.96	8.44
Fe^{2+} ion concentration (wt %)	2.44	2.38	2.32	1.94	1.88
Grain boundary resistivity ($\Omega \text{ m}$)	0.019	0.057	0.230	0.357	0.366
Grain resistivity ($\Omega \text{ m}$)	0.009	0.012	0.010	0.008	0.009
Saturation magnetization (G)	4319	4324	4319	4366	4280
Porosity	0.005	0.006	0.008	0.009	0.012

anisotropy, porosity, and eddy current loss. Therefore, the linewidth, ΔH of manganese–zinc ferrite polycrystals can be given as follows,¹¹

$$\begin{aligned}\Delta H &= \Delta H_{\text{anisotropy}} + \Delta H_{\text{porosity}} + \Delta H_{\text{eddy}} + \Delta H_{\text{others}} \\ &= \frac{8\pi\sqrt{3}}{21} \frac{H_A^2}{4\pi M_s} + \frac{8}{\sqrt{3}\pi} 4\pi M_s \frac{P_{\text{eff}}}{1+P_{\text{eff}}} + \Delta H_{\text{eddy}} \\ &\quad + \Delta H_{\text{others}},\end{aligned}\quad (2)$$

where H_A is anisotropy field, $4\pi M_s$ saturation magnetization, and P_{eff} is effective porosity.

In order to calculate the contribution of the anisotropy term, the anisotropy field in Eq. (2) should be known. The cubic anisotropy field ($H_A = 4K_1/3M_s$) was calculated using anisotropy constants reported by Hoekstra *et al.*¹² and the saturation magnetization in Table I. Hoekstra *et al.* reported that the anisotropy constant decreased from 1500 to 100 erg/cm³ with an increasing oxygen partial pressure. The anisotropy field calculated using these values decreased from 6 to 0.4 Oe with increasing oxygen partial pressure. These anisotropy fields contribute to a linewidth smaller than 0.1 Oe. So the contribution of the anisotropy field to the linewidth was negligible.

In Fig. 2, the contributions of anisotropy and porosity to the linewidth calculated using Eq. (2) are illustrated. The porosity term increased by 40 Oe with increasing oxygen partial pressure. Since the measured linewidth decreased 80 Oe with increasing oxygen partial pressure, the contribution of the ΔH_{eddy} term should be -120 Oe. Compared to the linewidth of the sample prepared under the lowest oxygen partial pressure, the magnitude of the ΔH_{eddy} term is larger than 60%. In Table I, the Fe^{2+} concentration decreased by 0.6 wt % with increasing oxygen partial pressure. Therefore, it can be suggested that the 0.6 wt % decrease in Fe^{2+} concentration of manganese–zinc ferrite polycrystalline sample was accompanied by a 60% decrease in their linewidth.

B. Linewidth versus eddy current loss

It is well known that eddy current loss is correlated with conductivity.⁵ In Table I, the change in grain boundary resistivity with oxygen partial pressure was 1 order of magnitude and thus appears to be responsible for the large contribution of the ΔH_{eddy} term. In our previous work, however, it was demonstrated that the change in grain boundary resistivity originated mainly from the change in grain boundary thickness. Furthermore, the capacitive grain boundary will be shorted at high frequency and thus will not contribute to the eddy current loss.

In Table I, the change in resistivity of grains with oxygen partial pressure is negligible. Since the eddy current loss

increases almost linearly with increasing conductivity we must address another mechanism for the broadening of linewidth. According to Galt and Clogston, the presence of Fe^{2+} ions in octahedral sites of spinel ferrites can cause a broadening of linewidth due to relaxation.^{13–15} For the sake of convenience, ferromagnetic resonance can be illustrated as precession of spins along the direction of the applied dc magnetic field. In other words, the magnetization direction is changing with time. Since Fe^{2+} and Fe^{3+} ions have different magnetic moments they tend to align themselves in order to minimize the free energy of the system. This rearrangement takes finite time and thus phase lag results in a line broadening.

V. CONCLUSIONS

It was suggested that the linewidth of manganese–zinc ferrite polycrystals decreased by 80 Oe with increasing oxygen partial pressure. The calculation of contributions of anisotropy and porosity to the linewidth revealed that the eddy current loss term was -120 Oe. It was suggested that 0.6 wt % decrease in Fe^{2+} concentration with increasing oxygen partial pressure was accompanied by a 60% decrease in the linewidth.

Since the decrease in the grain resistivity of the manganese–zinc ferrite was negligible, a relaxation mechanism was suggested to be responsible for the 60% decrease in the linewidth.

Oxygen tracer diffusion in polycrystalline nickel ferrites $\text{Ni}_{(1-x)}\text{Fe}_{(2+x)}\text{O}_{(4)}$ ($x=0.1; 0.2; 0.4$) at temperatures of 450–700 °C was studied. The number of ^{18}O atoms diffusing to the sample was determined using the $^{18}\text{O}(p,\alpha)^{15}\text{N}$ nuclear reaction at the energy of the primary beam particles equal to 762 keV. The nuclear physical experiments were performed on a 2 MV Van de Graaff accelerator. It has been established the oxygen diffusion is characterized by relatively small activation energy (0.89 eV for $x=0.2$) and low pre-exponential factors ($\sim 10^{-13} \text{ cm}^2/\text{s}$ for $x=0.2$). These results suggest that oxygen diffusion in the ferrites under consideration occurs by means of structural vacancies with their concentration about 10^{-9} – 10^{-11} . © 1998 American Institute of Physics. [S0021-8979(98)22511-4]

I. INTRODUCTION

This study has been performed to derive data on the oxygen tracer diffusion in ferrites, the parameters of the corresponding energy barriers, and the diffusion mechanism. The lack of information about the oxygen diffusion in ferrites has been the main reason for launching these investigations. In addition, the diffusion information may be helpful in analyzing the structural defects in the oxygen sublattice and straightforward determination of the limiting stage in the kinetics of the redox processes in ferrites. Thus, this study into diffusion may reinforce or demolish the existing concept on the fast (compared to anions) diffusion of cations (cation vacancies), which limits the kinetics of the redox processes in ferrites. One more important result may consist in ascertaining the presence of structural vacancies in the anion sublattice of ferrites and determining their concentration. This issue has long been debated. These and other findings relating to the oxygen diffusion kinetics are important for understanding the processes, which take place during the ferrite synthesis, thermal and thermomagnetic treatments, and operation of ferrites.

II. EXPERIMENT

To measure the diffusion coefficients of ^{18}O tracers, the samples underwent isothermal annealing in an ^{18}O -enriched oxygen atmosphere. Subsequently the concentration of the ^{18}O isotope was determined using the nuclear microanalysis method. By this method the concentration profiles $c(x)$ of ^{18}O atoms can be measured down to the depth of several microns without breaking the sample. Usually the diffusion coefficients are determined by solving Fick's second law for $c(x)$ taking the initial and boundary conditions of the diffusion problem realized in the experiment. In our case the preliminary experiments showed that the depth resolution of

the nuclear microanalysis method was insufficient for correct measurements of the $c(x)$ profiles. Therefore, in the nuclear physical experiments we determined the number of ^{18}O atoms per unit surface area Q of the annealed sample as a function of the annealing time t . The data were processed allowing for the presence of a certain number of ^{18}O atoms in the initial samples. It was also measured during the nuclear physical experiments. In terms of this approach, the diffusion coefficients D were calculated from the equation of Fick's second law for the function $Q(t)$. For the diffusion from a constant surface concentration source to a semi-infinite sample the solution of this equation is

$$Q = \frac{C_0}{\sqrt{\pi}} 2\sqrt{Dt}, \quad (1)$$

where C_0 is the concentration of the ^{18}O isotope on the surface of the sample. The value of C_0 was calculated using the expression

$$C_0 = \gamma C^0, \quad (2)$$

where γ is the degree of enrichment of oxygen with the ^{18}O isotope. In our experiments $\gamma=0.8$; C^0 is the oxygen concentration of the samples under study, which represented metastable cation-deficient spinels—analogs of the $\gamma\text{-Fe}_2\text{O}_3$ phase. As has been mentioned in the foregoing, the profiles $c(x)$ and the concentrations C_0 were not determined experimentally and therefore the only criterion confirming fulfillment of the boundary conditions of the diffusion problem was fulfillment of the dependence (1). Although this dependence was met quite well (as will be shown below), in the future we are going to obtain additional data, which would permit estimating more reliably the fulfillment of the boundary conditions of the diffusion problem. These data may include experimental measurements of the concentration profiles $c(x)$ allowing for an adequate depth resolution, or the concentration of ^{18}O atoms on the surface of the sample, C_0 ,

^{a)}Electronic mail: uinh@uinh.rcupi.e-burg.su

or the dependence $Q(t)$ analyzed for a wider interval of time than the interval used in this study. The experimental data reported in this article do not eliminate completely the systematic errors in measured D .

The ferrite samples, $\text{Ni}_{1-x}\text{Fe}_{2+x}\text{O}_4$, $x=0.1$, $x=0.2$ (samples No. 1 and No. 2), and $x=0.4$, were prepared by standard ceramic method using A. R. grade NiO , Fe_2O_3 . The powders of these oxides were mixed in desired proportions and were ground in an automatic agate mortar under ethanol for 35 h. The dried powders were mixed with polyvinyl alcohol and water and were pressed into 1.3 cm diameter pellets. These samples were fired at 900 °C for 15 h, then they were ground again and were formed into pellets in the same manner. Final sintering was done in a furnace at 1250 °C for 10 h. The completion of the solid state reaction was checked by the x-ray diffraction studies. It has been established from radiography and microstructural data that all samples were single phase spinels with the following crystal lattice parameters: 0.8342(9) nm ($x=0.1$); 0.8346(6) nm ($x=0.2$); and 0.8355(2) nm ($x=0.4$). The mean crystallite size was about 10 μm . Samples No. 1 and No. 2 were synthesized from different starting materials and had the same chemical composition. Prior to diffusion annealing in the ^{18}O atmosphere at a preset temperature, the samples were annealed in the ^{16}O atmosphere at the same temperature until its mass was constant. As a result, the samples were oxidized up to saturation through the formation of metastable cation-deficient spinels. It was confirmed by an x-ray examination.¹ The aim of this treatment was to separate the oxygen self-diffusion process and the oxidation process, which leads to an increase in the number of oxygen atoms in the lattice. According to the x-ray data, ferrites with $x=0.4$ have two phases if they are annealed at a temperature of 550 °C or higher. The samples with more than one phase in the structure were excluded from consideration.

The oxide samples had a flat surface 5×5 mm in size and were several millimeters thick. Diffusion annealings were performed at the oxygen pressure of 0.21 atm. The volume of the quartz tube was sufficiently large to rule out a marked change in the isotope composition of the gas during annealing. This was confirmed by special experiments where oxygen was and was not replaced in the quartz tube during annealings and then the concentrations of ^{18}O and ^{16}O isotopes were measured in the samples. Subsequent to isothermal annealing, the samples were cooled to room temperature and the concentration of ^{18}O atoms was determined in the samples. One and the same sample was used to study the dependence $Q(t)$ at each temperature, i.e., every sample was heated repeatedly to the preset annealing temperature and then was cooled to room temperature. The nuclear physical measurements were made after every heating/cooling cycle. The time required to reach a constant temperature was less than 10 min, while the cooling time was approximately 1 min. The temperature was measured with an accuracy of ± 1 °C using a chromel–alumel thermocouple. The quartz tube was placed in a massive metal cylinder during annealings. This arrangement eliminated a temperature gradient at the samples within the said accuracy limits.

The number of ^{18}O atoms diffusing to the sample was

FIG. 1. The number of ^{18}O atoms per unit surface area of samples $\text{Ni}_{1-x}\text{Fe}_{2+x}\text{O}_4$ vs annealing time.

determined using the $^{18}\text{O}(p, \alpha)^{15}\text{N}$ nuclear reaction at the energy of the primary beam particles equal to 762 keV. The nuclear physical experiments were performed on a 2 MV Van de Graaff accelerator. The proton beam diameter was 1 mm, i.e., the measured Q was averaged over a large number of crystallites. The test flat surface of the samples was placed perpendicular to the axis of the primary beam. The nuclear reaction products were registered at an angle of 160°. The energy spectrum of these products was measured by a silicon surface-barrier detector about 1 cm in diameter. The standard deviation of the measured Q was less than 5%. The nondestructive measurements were made down to a depth of about 2 μm . The ^{18}O atoms were found to penetrate to the samples for not more than 0.2 μm .

As has been mentioned in the foregoing, Q was determined several times at random places on every sample. According to the preliminary experiments, the distribution inhomogeneity of the ^{18}O atoms on the test surface of the samples could be as high as 15%.

III. RESULTS AND DISCUSSION

Figure 1 shows the dependence $Q(t)$ for ferrite samples having different compositions at several temperatures of diffusion annealing. One may see that in all the instances the dependences, which correspond to the solution (1) of Fick's second law, are reasonably fulfilled over a wide interval of time. The deviation of Q from the linear dependences does not exceed the experimental errors. These errors are due mainly to different rates at which ^{18}O atoms arrive to various areas of the samples, i.e., to their inhomogeneity in terms of diffusion. The accuracy of the nuclear physical measurements makes a smaller contribution to the experimental errors.

The measured diffusion coefficients are presented in Fig. 2. Note first that in all the instances the diffusion coefficients

FIG. 2. Temperature dependence of diffusion coefficients of oxide ions in $\text{Ni}_{1-x}\text{Fe}_{2+x}\text{O}_4$ ceramics.

of the ^{18}O atoms measured by us proved to be much lower than those reported in literature^{2,3} for iron atoms in spinels of the analogous composition, which were measured at similar temperatures or extrapolated to the temperature interval of 500–700 °C. This fact suggests that the limiting stage in oxidation or reduction of spinel-like magnetites is the diffusion of oxygen cations rather than anions. It supports the conjectures on the mechanism of the redox reactions.² Let it be noted that the low values of the oxygen diffusion coefficients are due to a very small pre-exponential factor D_0 in the temperature dependence $D = D_0 \exp(-E/kT)$. In the case of the sample having the composition $\text{Ni}_{0.8}\text{Fe}_{2.2}\text{O}_4$ (sample No. 1) $D_0 = 4.68 \times 10^{-13} \text{ cm}^2/\text{s}$, whereas for cations D_0 is of the order of $10^{-4} \text{ cm}^2/\text{s}$.²

One more important conclusion may be drawn from the analysis of D_0 and the diffusion activation energy E determined in this study. They adduce a unique evidence that in the samples at hand oxygen atoms diffuse through structural vacancies rather than thermal equilibrium vacancies in the oxygen sublattice. This inference is supported, first, by a low diffusion activation energy $E = (0.89 \pm 0.1) \text{ eV}$. When thermal equilibrium vacancies are involved in diffusion, the diffusion activation energy is equal to the sum of the oxygen atom migration energy E_m and the vacancy formation energy E_f : $E = E_m + E_f$. However, E_f usually exceeds 1 eV.⁴ On the other hand, if diffusion involves thermal equilibrium and structural vacancies, the order of the pre-exponential factor D_0 is roughly determined by the respective expressions⁵

$$D_0 \sim a^2 \nu \quad \text{and} \quad D_0 \sim a^2 \nu n_v, \quad (3)$$

where $a \sim 10^{-8} \text{ cm}$ is the lattice constant; $\nu \sim 10^{12} \text{ s}^{-1}$ is the vibration frequency of oxygen atoms in the lattice; n_v is the concentration of structural vacancies. Taking into account the value of D_0 found in this study, the order of the concentration of structural vacancies may be estimated at $10^{-9} - 10^{-11}$ (this range allows for some uncertainty in the values of ν and more complicated expressions for D_0 , which contain other parameters⁵). It has been mentioned in the Introduction that the presence of structural vacancies in the oxygen subsystem of ferrites is questionable. Therefore this result may be treated as the first attempt (to the best of our knowledge) to measure directly the concentration of structural oxygen vacancies in these compounds. Note that such small concentrations of structural vacancies can hardly be measured by other techniques.

One more challenge of this study was to analyze the effect of the chemical composition of the cation sublattice of the ferrite on the diffusion coefficient of oxygen tracers. But we have failed to meet this challenge because of uncontrolled factors. From Fig. 2 it is seen that in samples synthesized from different starting materials and having the same chemical composition the oxygen diffusion coefficients differ by two orders of magnitude. A probable cause for this large difference in the diffusion coefficients in the samples No. 1 and No. 2 is the doping of the cation sublattice with impurities, which was not controlled in our experiments. The most probable uncontrolled impurities in the samples studied may be Ca, Se, Cu, and V. For example, doping of the cation sublattice of ZnO with impurities at the level of 0.3 at. % was shown⁶ to change the diffusion coefficient of ^{18}O tracers by one or two orders of magnitude. Clearly these large uncontrolled changes in the diffusion coefficient made it impossible to derive reliable information concerning the effect of the nickel content on the oxygen diffusion coefficient in nickel ferrites.

One more point is worth noting. A very low value of the oxygen diffusion activation energy (0.89 eV) and the corresponding high mobility of structural oxygen vacancies indicate that oxygen vacancies may participate in the local rearrangement of the structure during the processes that determine the thermomagnetic properties of ferrites.

Conversion electron Mössbauer studies on strontium ferrite films with in-plane and perpendicular anisotropies

Antony Ajan,^{a)} B. Ramamurthy Acharya,^{b)} Shiva Prasad, and S. N. Shringi
Department of Physics, Indian Institute of Technology, Bombay-400 076, India

N. Venkataramani

ACRE, Indian Institute of Technology, Bombay-400 076, India

Hexagonal strontium ferrite thin films with in-plane and perpendicular magnetic anisotropies have been studied using conversion electron Mössbauer spectroscopy. The hyperfine parameters of the films were found to be similar to the one obtained for bulk strontium ferrite. However, the intensity ratios of the first and second lines of the Mössbauer spectra were found to be different for films deposited at different rf powers. This indicated a change in the anisotropy of the deposited film. The resultant change in the magnetization direction and crystallization texture was compared to other measurements. © 1998 American Institute of Physics. [S0021-8979(98)20111-3]

I. INTRODUCTION

Recently a number of materials has been investigated for application as thin film media for high density recording. Hexagonal ferrite ($\text{BaFe}_{12}\text{O}_{19}$ and $\text{SrFe}_{12}\text{O}_{19}$) thin films are investigated due to their possible application in longitudinal and perpendicular recording media.¹⁻⁴ In addition to their chemical stability and mechanical hardness, hexagonal ferrite media in both particulate and thin film mode have been shown to exhibit lower recording noise.¹⁻³ In thin film form it is important to control the crystallographic texture, microstructure, and magnetic properties for such applications. The properties of these thin films can be significantly varied by changing the deposition conditions.

Mössbauer studies have been used in past to give information about the magnetic ordering, cation distribution, valence levels, impurity, etc. in ferrites. Mössbauer studies on bulk polycrystalline strontium ferrite has also been reported.⁵⁻⁷ In strontium ferrite, Fe^{3+} is located at five different types of sites which are denoted in literature as $12k$, $4f_1$, $4f_2$, $2a$, and $2b$.⁵⁻⁷ Since Fe^{3+} in different sites has different hyperfine parameters, the resultant Mössbauer spectrum is a superposition of five subspectra corresponding to five different Fe^{3+} sites. The ratio of the area under the subspectra gives the ratio of occupation of these sites. In the case of the reported bulk Mössbauer spectra only four six-line Mössbauer patterns have been resolved. The hyperfine parameters of $4f_1$ and $2a$ are close to each other and hence not resolved for polycrystalline materials. In this article we report on the conversion electron Mössbauer spectroscopy (CEMS) study of strontium ferrite films deposited by rf sputtering under various conditions. The results obtained were compared with the Mössbauer studies on bulk.

II. EXPERIMENTAL DETAILS

The strontium ferrite films were deposited by rf sputtering using a Leybold Z400 sputtering unit. The films were

deposited at two different rf powers of $P=60$ and 330 W (power densities of 1.3 and 7.5 W/cm², respectively) and two different O_2/Ar gas ratios of $R=1.5\%$ and 15% . These films were prepared on 2 in. diam Si(111) wafers, and were enriched with ^{57}Fe by placing a small quantity of enriched Fe_2O_3 on the strontium ferrite target. The use of films with larger areas and with enrichment by ^{57}Fe is for enhancement of the signal to noise ratio in the Mössbauer spectra. The distance between the target and the substrate was maintained at 50 mm. At $P=60$ W, the deposition rates were 13 and 10 Å/s for $R=1.5\%$ and 15% , while for $P=330$ W, they were 40 and 37 Å/s respectively. The films were prepared at ambient temperatures and were then annealed at 800°C for 3 h in air. Films of ≈ 240 nm thickness were used in this study.

The Mössbauer spectra for the target material were recorded in transmission mode by taking a small portion of the material from the target used for sputtering. Mössbauer spectra of the thin films were recorded using the scattering mode (CEMS). A 10 mci ^{57}Co source on a Rh matrix was used as the Mössbauer source.

III. RESULTS AND DISCUSSIONS

In Fig. 1 a Mössbauer spectrum for the bulk target material is shown. The hyperfine parameters were obtained from the least square fit method. The hyperfine parameters ob-

tained for the bulk sample are listed in Table I. The hyperfine parameters obtained agree well with the reported values for bulk strontium ferrite.

The Mössbauer spectrum for one of the as-deposited films is shown in Fig. 2. The as-deposited films show a paramagnetic doublet spectrum. Magnetization data on as-deposited samples show a similar result.⁸ Mössbauer spectra of the crystallized films deposited at different rf powers and different O₂/Ar ratios are shown in Fig. 3. All the spectra look identical except the second and fifth peaks which are positioned at ≈ -4 and $+4$ mm/s, respectively. The intensities of the second and fifth lines are comparatively high for the film which is deposited at higher power, i.e., 300 W compared to the film deposited at a lower power (60 W).

The hyperfine parameters were obtained from the least square fit method by fitting Lorentzian lines. The values of different parameters like hyperfine field, isomer shift, quadrupole splitting, and the intensity ratios of the first and sec-

FIG. 2. Conversion electron Mössbauer spectrum for the as-deposited strontium ferrite film on Si(111), deposited at rf power = 60 W and on O₂/Ar ratio of 15%.

ond lines of subspectra (b) were iterated to obtain the best fit. The intensity of the second and fifth lines, (b), was taken to be the same for all the subspectra. This is because of the spin structure of SrFe₁₂O₁₉, where spins of Fe³⁺ at different sites are parallel to the *c* axis. The various parameters of the fitted Mössbauer spectra are listed in Table I. A comparison of these parameters with the bulk strontium ferrite values shows that the ratios of the area under different subspectra match well with bulk values within an error of $\pm 4\%$. This shows that the strontium ferrite films have a nearly stoichiometric composition and a cationic distribution like that of the bulk. The presence of any second phase would have led to a modification in the spectra from the bulk. Hyperfine field values obtained for all the samples agree well with the bulk sample. The isomer shift (IS) as well as the quadrupole shift (QS) values are also found to agree within the experimental error

FIG. 3. Conversion electron Mössbauer spectra for strontium ferrite films on Si(111) with different powers and O₂/Ar ratios.

TABLE II. Magnetic properties of strontium ferrite thin films deposited under different conditions.

Sample	Power (W)	O ₂ /Ar (%)	H _c (kOe)		M _s (emu/cc)	M _r /M _s	
				⊥			⊥
A	60	1.5	3.9	4.1	240	0.50	0.94
B	60	15	3.1	3.4	270	0.45	0.98
C	330	1.5	3.9	3.7	280	0.60	0.55
D	330	15	3.6	3.5	275	0.70	0.61

(± 0.04 mm/s). indicates the chemical as well as the structural environments in thin film form are identical with the bulk strontium ferrite.

The **b** value, which indicates the local magnetic moment direction with respect to the incident γ ray direction, was found to vary significantly with the rf power and the O₂/Ar ratio. For film deposited at the 60 W the **b** value decreases from 1.2 to 0.9 as the O₂/Ar ratio increases from 1.5% to 15%. This **b** value, lower than 2, indicates that the magnetic moment direction tends to lie perpendicular to the plane of the film. The orientation is better for a higher O₂/Ar ratio. For a film deposited at 330 W the **b** value increases from 2.2 to 2.8 as the O₂/Ar ratio increases from 1.5% to 15%. This **b** value, higher than 2, indicates that the magnetic moment direction tends to lie in the plane of the film. Again the orientation is better for a higher O₂/Ar ratio. Thus our results indicate that for the same rf power the orientation improves with a higher O₂/Ar ratio. A value of **b**=2 indicates that a random orientation was found from fitting the bulk polycrystalline powder sample. The x-ray diffraction (XRD) studies⁸ carried out on Sr ferrite films deposited at 60 W and at different O₂/Ar ratio show a predominant *c*-axis orientation perpendicular to the film plane. The sample deposited at higher power ($P=330$, W) and with a different O₂/Ar ratio had a predominant *c*-axis orientation in the film plane. The easy axis was randomly distributed within the film plane.

The magnetic properties of the films used in this study are listed in Table II.

The coercivity (H_c) values decrease from 4.1 kOe for the sample deposited at 60 W with a 1.5% O₂/Ar ratio to 3.4

kOe for the sample deposited at 60 W with a 15% O₂/Ar ratio. Similarly, the H_c values decrease from 3.7 kOe for the sample deposited at 330 W with a 1.5% O₂/Ar ratio to 3.4 kOe for the sample deposited at 330 W with a 15% O₂/Ar ratio. Other properties such as M_r/M_s , etc. also show a considerable change with the change in the O₂/Ar ratio, as is evident from Table II. Large M_r/M_s confirms that samples with 60 W power have a perpendicular orientation.

It is interesting to note that even though the orientation is better for a higher O₂/Ar ratio the coercivity is comparatively small. A study by Acharya *et al.*⁹ on these samples indicated that intergranular interaction increases with the O₂/Ar ratio. This intergranular interaction could be the cause for the reduced coercivity in these films even though the orientation has improved with increasing O₂/Ar ratio.

IV. CONCLUSION

Hyperfine parameters obtained from Mössbauer analysis were found to be similar in bulk and in thin film samples. The **b** value, on the other hand, is found to be different from the bulk and was also dependent on power and the O₂/Ar ratio. This indicates textured growth in these films which was confirmed by XRD studies.⁹ These studies indicate that by varying the deposition condition we could achieve films with either the easy axis parallel to or perpendicular to the plane of the film. This information can be very useful for longitudinal and transverse magnetic recording.

Using neutron diffraction techniques, we have directly characterized the antiferromagnetic spin structure of CoO in exchange-biased $\text{Fe}_3\text{O}_4/\text{CoO}$ (001) superlattices. The CoO antiferromagnetic order is long-range and extends coherently across intervening ferrimagnetic Fe_3O_4 layers. The ordering is influenced significantly by not only epitaxial growth constraints but also by coupling to the Fe_3O_4 layers. The antiferromagnetic order in these $\text{Fe}_3\text{O}_4/\text{CoO}$ (001) samples exhibits significant dependence on field cooling preparations. The CoO spins show a strong tendency to align perpendicular to the net ferrimagnetic moment with some changes in the average domain size associated with field cooling. The CoO spin structure in the exchange-biased state illustrates important aspects of recent biasing theories but with unusually large domain sizes. © 1998 American Institute of Physics. I. INTRODUCTION

Recently, there has been a renewed interest in studying magnetic systems exhibiting exchange anisotropy or exchange biasing.¹⁻⁷ First discovered in the 1950s,⁸ these systems typically consist of ferromagnetic (FM) materials in contact with antiferromagnetic (AFM) materials. Due to exchange-coupling between the FM and AFM layers, a host of unusual magnetic behavior is observed, including a field shift or *bias* in the FM hysteresis loop after field cooling through the AFM ordering temperature (T_N). Despite over 40 years of experimental and theoretical effort, there is still considerable debate about the mechanisms for this exchange-biasing effect. In particular, recent theories have concentrated on the detailed role of AFM domain wall formation as an essential element to understanding the exchange anisotropy.⁹⁻¹¹ The nature of the AFM and FM coupling at the interface is also under discussion, as well as the ideal AFM spin configuration for maximal biasing effect. In most experiments, the interfacial behavior of the antiferromagnet is usually inferred from bulk measurements or from the FM response.^{6,7} In contrast, elastic neutron diffraction provides a method to determine directly the nature of the AFM order in such systems.¹²

In this article, we discuss neutron diffraction results that directly focus on the CoO AFM behavior in exchange-biased $\text{Fe}_3\text{O}_4/\text{CoO}$ (001) superlattices. The growth of crystalline superlattices is possible because the spinel Fe_3O_4 and rock salt CoO structures have similar bulk lattice parameters ($a_{\text{Fe}_3\text{O}_4} = 8.398 \text{ \AA}$ and $2a_{\text{CoO}} = 8.508 \text{ \AA}$) and have complementary oxygen sublattices in the (001) plane.^{4,13} By growing superlattices with thin layers and multiple repeats, we can highlight the interfacial region which is of interest for exchange-

biasing. In addition, the bulk properties of both CoO and Fe_3O_4 have been studied extensively.^{14,15} Bulk CoO orders antiferromagnetically below $\sim 291 \text{ K}$ in ferromagnetic sheets that alternate sign along $\langle 111 \rangle$ "propagation" directions, leading to distinct $\{111\}$ domains. Bulk Fe_3O_4 orders ferrimagnetically below $\sim 858 \text{ K}$ with a net moment of $4.2 \mu_B$ per unit cell. As demonstrated previously, the $\text{Fe}_3\text{O}_4/\text{CoO}$ (001) system exhibits substantial exchange-biasing, despite the fact that the CoO (001) *interface* is expected to be compensated with no net moment.⁴ Thus, the $\text{Fe}_3\text{O}_4/\text{CoO}$ system is a good model to study the role of the antiferromagnet in producing biasing.

For superlattices of this system, we find that the CoO AFM ordering is long-range and propagates coherently through intervening Fe_3O_4 layers. The Co moment directions are constrained by sample epitaxy and influenced as well by perpendicular coupling to the ferrimagnetic Fe_3O_4 layers. Upon field cooling and field cycling, subtle changes in the AFM domain sizes are observed. These features are illustrative of the complex role of the antiferromagnet in exchange-biased systems.

II. EXPERIMENTAL DETAILS

Two $\text{Fe}_3\text{O}_4/\text{CoO}$ superlattices, $[\text{Fe}_3\text{O}_4 (100 \text{ \AA})/\text{CoO} (30 \text{ \AA})]_{50}$ and $[\text{Fe}_3\text{O}_4 (100 \text{ \AA})/\text{CoO} (100 \text{ \AA})]_{50}$, were grown by oxidic molecular beam epitaxy (MBE) onto 1.6 cm diameter [001] MgO substrates. Reflection high energy electron diffraction and x-ray scattering measurements show that the deposition results in epitaxial [001] superlattices with rocking curve full widths at half maximum (FWHM) of $\sim 0.2^\circ$ and interfacial widths of $\sim 2 \text{ \AA} \pm 1 \text{ \AA}$. For comparison, a third

FIG. 1. Schematic showing the reciprocal space reflections discussed in the text as well as the directions in which the samples were field cooled. The scan directions through each peak are designated with small arrows.

superlattice with nonmagnetic MgO as spacer layers $[\text{MgO} (30 \text{ \AA})/\text{CoO} (30 \text{ \AA})]_{333}$ was also grown by MBE onto an [001] MgO substrate.

After preliminary characterization by x-ray analysis, neutron diffraction data were obtained on three triple-axis spectrometers (BT-2, BT-9, and SPINS) at the National Institute of Standards and Technology. For unpolarized measurements (BT-2 and BT-9), a pyrolytic graphite (PG) monochromator and analyzer were used to select elastically scattered neutrons of energy 14.8 meV. Typical collimation of $40' - 48' - 48'$ resulted in resolution in the growth direction of ~ 0.012 to 0.030 \AA^{-1} for all of the reflections of interest. For polarized measurements (SPINS), a supermirror polarizer and an Al coil spin flipper were positioned before and after the sample to select all four neutron spin cross sections, $[(++)$, $(--)$, $(+-)$, and $(-+)$], with polarization efficiencies greater than 91%.¹⁶ The + and - signs denote the neutron polarization before or after scattering from the sample.

For these experiments, the samples were oriented vertically with the [110] in-plane axis and [001] growth direction defining the scattering plane as shown in Fig. 1. The superlattices were cooled in a 14 kOe field applied in several directions within the sample growth plane. The specific reflections studied and the directions of the scans are also illustrated in Fig. 1.¹⁷ In these superlattices and consistent with bulk structure factor calculations,^{12,14} the {111} class of reflections have the strongest contribution from the CoO AFM order. The (331) and (113) reflections provide additional information about the CoO magnetic ordering, whereas the (222) reflection has only a structural contribution from the CoO. The Fe_3O_4 structural and magnetic order contributes to all these reflections and is solely responsible for the (220) reflection. For the three superlattices, the (222) satellite reflections were nearly resolution limited in the growth axis direction, indicating that the structural coherence is long range.

III. RESULTS AND DISCUSSION

A. Zero field characterization

The AFM order of the superlattices was first characterized in zero field. Figure 2(a) shows typical neutron diffrac-

FIG. 2. Neutron diffraction scans along the [001] Q_z direction through the (a) (111) and (b) (220) reflection. The circles (\circ) refer to the $[\text{MgO} (30 \text{ \AA})/\text{CoO} (30 \text{ \AA})]_{333}$ at 15 K, and the triangles (Δ) refer to the $[\text{Fe}_3\text{O}_4 (100 \text{ \AA})/\text{CoO} (30 \text{ \AA})]_{50}$ superlattice at 28 K, both normalized to the peak values. The MgO/CoO data has been displaced from the origin by a factor of 0.2 for clarity. Solid lines denote fits to Gaussians. The dashed lines in the (111) scan show the broad Gaussians associated with the Fe_3O_4 component. The double-headed arrows indicate the width of the broad features in the $[\text{Fe}_3\text{O}_4 (100 \text{ \AA})/\text{CoO} (30 \text{ \AA})]_{50}$ reflection.

tion scans of the (111) reflection along the [001] direction. As illustrated in the figure, the line shapes differ quite significantly for the MgO/CoO sample as compared to the exchange-biased $\text{Fe}_3\text{O}_4/\text{CoO}$ samples.

For the unbiased MgO/CoO superlattice, the (111) structural reflection is forbidden such that the diffracted intensity originates entirely from the AFM CoO ordering. The broad line shape in this case indicates that the magnetic order has limited coherence along the growth axis direction. Considering the full width at half maximum and the instrumental resolution, we find that the magnetic coherence length is $\sim 35 \pm 5 \text{ \AA}$ and is thus restricted to a single CoO layer. This result is not surprising given that the MgO spacers are nonmagnetic and that the superexchange interaction in bulk CoO is short range.¹⁴ The temperature dependence of the AFM ordering is also consistent with bulk CoO, as the intensity of the (111) reflection decreases to zero at $T_N = 300 \pm 10 \text{ K}$, as compared with the bulk AFM CoO $T_N \sim 291 \text{ K}$.

In contrast, for the two $\text{Fe}_3\text{O}_4/\text{CoO}$ superlattices, the (111) reflection senses the CoO AFM order as well as the structural and magnetic ordering of the Fe_3O_4 . In these samples, the scattering contributions from the two oxides can be distinguished by the differences in line shape and temperature dependence. As illustrated in Fig. 2(a) for the $\text{Fe}_3\text{O}_4 (100 \text{ \AA})/\text{CoO} (30 \text{ \AA})$ sample, the $\text{Fe}_3\text{O}_4/\text{CoO}$ (111) reflection in the growth direction shows a two-component line shape with a broad and narrow contribution.

The magnitude of the broad component is not sensitive to temperature for the range of $T = 10$ to 600 K which is well below the ordering temperature of bulk Fe_3O_4 (858 K). As shown in Fig. 2(b), the (220) reflection, which is solely due to the Fe_3O_4 layers, is also quite broad. For both samples, these broad peak widths give coherence lengths of ~ 100 Å along the growth axis direction which correspond to the width of a single Fe_3O_4 layer. These data indicate that the registry of the Fe_3O_4 spinel lattice is not retained across the intervening CoO interlayers. This lack of coherence is not surprising due to the nonunique alignment of the Fe tetrahedral sites in the spinel relative to the rock salt CoO template at each Fe_3O_4 /CoO interface. Thus, the differences in the two crystal structures is expected to result in some type of structural disorder.¹⁸ In particular, the existence of stacking faults in the Fe_3O_4 layers has been observed and modeled extensively in Fe_3O_4 /NiO superlattices.¹² These structural faults thus lead to the broadened peak widths observed in Fig. 2. Note that these reflections have both a magnetic and structural component from the Fe_3O_4 layers. Due to the broadening from structural features, the magnetic coherence length of the Fe_3O_4 is masked and may in fact still be long range.

As the broad component of the (111) reflection tracks the Fe_3O_4 structural and magnetic order, the narrow component measures the CoO AFM order. We note that the magnitude of the narrow component is sensitive to temperature. Upon heating, this intensity decays smoothly to zero at temperatures near or above the bulk CoO T_N value of 291 K. Specifically, the AFM ordering temperatures as determined by this method are 450 ± 15 K for the $[\text{Fe}_3\text{O}_4(100 \text{ Å})/\text{CoO}(30 \text{ Å})]_{50}$ superlattice and 325 ± 15 K for the $[\text{Fe}_3\text{O}_4(100 \text{ Å})/\text{CoO}(100 \text{ Å})]_{50}$ superlattice. The apparent increase in the AFM ordering temperature with increasing relative Fe_3O_4 thickness is consistent with observations in a series of Fe_3O_4 /CoO superlattices as well as for Fe_3O_4 /NiO and NiO/CoO samples.^{12,19,20} These changes are in agreement with mean-field simulations of the exchange coupling between the Co and Fe spins at the superlattice interfaces.¹² In addition to alterations in the CoO ordering temperature, we note that the CoO line width is much more narrow than for the MgO/CoO superlattice [Fig. 2(a)]. Thus, in both Fe_3O_4 /CoO samples, the AFM order is long range along the growth axis direction. Considering the full width at half maximum (FWHM) deconvoluted by the instrumental resolution, we find that the magnetic coherence lengths are always greater than 300 Å and in some cases greater than 800 Å. This long-range order may result from local exchange coupling to the Fe_3O_4 at the superlattice interfaces. Apparently, the alternation of the Fe_3O_4 moments preserves the phase of the CoO AFM order from one layer to the next. Scanning in the growth plane, we find that the CoO AFM order is also long range.

B. Moment direction determination

To determine the AFM moment directions within each {111} domain, we examined the three superlattices with polarized neutron diffraction. Figures 3(a)–3(c) shows typical polarized neutron diffraction data of the (111) reflection scanned in the [001] direction for the three samples taken at

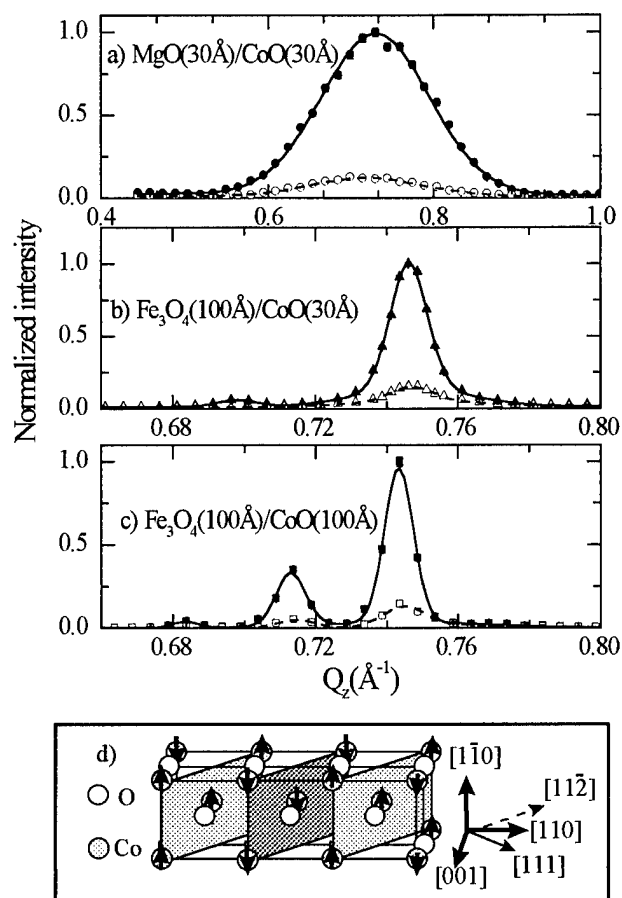

FIG. 3. Polarized neutron diffraction scans of the (111) reflection along the [001] direction for the (a) \circ $[\text{MgO}(30 \text{ Å})/\text{CoO}(30 \text{ Å})]_{333}$, (b) \triangle $[\text{Fe}_3\text{O}_4(100 \text{ Å})/\text{CoO}(30 \text{ Å})]_{50}$, and (c) \square $[\text{Fe}_3\text{O}_4(100 \text{ Å})/\text{CoO}(100 \text{ Å})]_{50}$ superlattices after cooling in a 14 kOe along the [110] direction to 78 K. The closed symbols denote the nonspin flip scattering which is sensitive to the CoO moment along [110]. The open symbols denote the spin flip scattering which is sensitive to the CoO moments along the [112] direction. (d) Illustration of the spin structure as determined from the above diffraction data.

78 K. In these measurements with the sample orientation as in Fig. 1, the nonspin flip $[(++)$ and $(--)]$ intensities are sensitive to the AFM CoO moment contribution parallel to the [110], while the spin flip $[(+-)$ and $(-+)]$ intensities are sensitive to the AFM CoO moment component parallel to the [112] direction. As illustrated in the figure, for all three superlattices, the non-spin flip contribution dominates the spin flip, indicating that the AFM moments associated with the (111) reflection lie along the [110] direction. The small amount of CoO spin flip scattering detectable is at the efficiency limit of the polarizing elements. Thus to within $\pm 2^\circ$, nearly all the Co spins within the alternating ferromagnetic sheets point in the $\pm[110]$ direction for the (111) domain, as illustrated in Fig. 3(d).²¹ This moment orientation persists to the AFM ordering temperature and did not change as a function of field cooling in three different directions within the growth plane, namely in the [110], [110], and [100] directions. The intensities observed for the (331) and (113) antiferromagnetic reflections confirm that the AFM moments are essentially confined to the (111) plane.

For this (111) domain, the alignment of the Co moments along this single [110] direction within the sample growth

FIG. 4. Neutron diffraction scans along the $[001] Q_z$ direction through the (111) reflection after zero field cooling and field cooling in 14 kOe field along the $[\bar{1}\bar{1}0]$ direction to 78 K. Data are normalized to the zero field cooled data. The circles (\circ and \bullet), squares (\square and \blacksquare), and triangles (\triangle and \blacktriangle) refer to the $[\text{MgO}(30\text{ \AA})/\text{CoO}(30\text{ \AA})]_{333}$, $[\text{Fe}_3\text{O}_4(100\text{ \AA})/\text{CoO}(30\text{ \AA})]_{50}$, and $[\text{Fe}_3\text{O}_4(100\text{ \AA})/\text{CoO}(100\text{ \AA})]_{50}$ superlattices, respectively. Open symbols refer to the zero field cooled data, and closed symbols refer to the field cooled data. Dashed lines indicate the broad Fe_3O_4 contribution.

plane contrasts with the behavior of bulk CoO, which has three different moment directions ($[\bar{1}\bar{1}3]$, $[\bar{1}\bar{3}\bar{1}]$, and $[3\bar{1}\bar{1}]$) canted out of the (111) plane by 8° .¹⁴ These data suggest that the CoO spin structure in these superlattices is altered as a consequence of epitaxial growth constraints. We note that the bulk lattice parameter of CoO differs from that of Fe_3O_4 and that of the substrate MgO by $\sim 1.0\%$ – 1.5% .

C. Field-dependent domain characteristics

While the antiferromagnetic moment *directions* are influenced by structural features, the *number* of spins aligned in these directions is determined by the nature of the interfacial coupling as revealed by field-dependent measurements. Figure 4 shows the results at remanence after cooling the three superlattices from 320 to 78 K in a 14 kOe field applied in the $[\bar{1}\bar{1}0]$ direction. The data are scaled against similar data obtained after cooling to 78 K in zero applied field.

For the MgO/CoO superlattice, the field cooling treatment leads to little change in the intensity of the (111) reflection relative to the zero field cooled state. The applied magnetic field appears to have little effect on the AFM CoO order. This lack of a field response is not surprising in that the applied field of 14 kOe is roughly an order of magnitude less than the typical fields in which many antiferromagnets undergo a spin flop transition and align mostly perpendicular to the applied field.²²

FIG. 5. The relative integrated intensity of the CoO contribution to the (111) reflection scanned along the $[001]$ direction after cooling from 320 K to 78 K in a 14 kOe field applied in different directions within the sample growth plane. The triangles (\triangle) refer to the $[\text{Fe}_3\text{O}_4(100\text{ \AA})/\text{CoO}(30\text{ \AA})]_{50}$ and the squares (\blacksquare) to the $[\text{Fe}_3\text{O}_4(100\text{ \AA})/\text{CoO}(100\text{ \AA})]_{50}$ superlattices. The data are normalized to data obtained after zero field cooling to 78 K as indicated by the solid line. For the 100 Å sample, the zero field data was obtained after randomizing the Fe_3O_4 magnetization by successively decreasing cycles of the field at 350 K. Lines between points are a guide to the eye.

In contrast, both of the $\text{Fe}_3\text{O}_4/\text{CoO}$ superlattices [Figs. 4(b)–4(c)] show a significant decrease in the (111) intensity upon field cooling in the $[\bar{1}\bar{1}0]$ direction, as CoO spins are driven out of this (111) domain. Note that this change is associated with the narrow CoO contribution and not the broader Fe_3O_4 component. This field effect is large relative to that observed for nonmagnetic MgO spacers and indicates the importance of the coupling of the AFM CoO moments to the Fe_3O_4 layers.

The nature of this coupling is apparent when considering the effect of field cooling in different directions within the sample growth plane. Figure 5 shows the integrated CoO intensity at the (111) reflection in remanence after field cooling along the $[110]$, $[100]$, and $[\bar{1}\bar{1}0]$ directions. The field cooling data have been normalized against comparable zero field cooled data which has been set to 0.5. For both $\text{Fe}_3\text{O}_4/\text{CoO}$ samples, the AFM (111) intensity is *highest* upon field cooling in the $[110]$ direction, as CoO spins are driven *into* the (111) domain. From the polarized beam data discussed in the previous section, we have determined that the AFM spins in the (111) domain are lined up along the $\pm[\bar{1}\bar{1}0]$ direction irrespective of field treatment. Thus, the preferred orientation of the AFM spins in the (111) domain is *perpendicular* to the net ferrimagnetic moment, which is aligned along the $[110]$ applied field direction. The extent to which this perpendicular arrangement is preferred is different for the two samples, as the field cooling effect is more pronounced for the $[\text{Fe}_3\text{O}_4(100\text{ \AA})/\text{CoO}(100\text{ \AA})]_{50}$ superlattice than for the $[\text{Fe}_3\text{O}_4(100\text{ \AA})/\text{CoO}(30\text{ \AA})]_{50}$ sample. This difference is also consistent with magnetization measurements on these samples. The $[\text{Fe}_3\text{O}_4(100\text{ \AA})/\text{CoO}(100\text{ \AA})]_{50}$ superlattice showed a much larger field shift for the hysteresis loop at 78 K as compared to the $[\text{Fe}_3\text{O}_4(100\text{ \AA})/\text{CoO}(30\text{ \AA})]_{50}$ sample (1300 ± 100 Oe vs 550 ± 50 Oe).²⁰

The direct observation of field-cooling dependent changes in the AFM (111) intensity agrees with most current models of exchange-biasing, to the degree that the nature of

FIG. 6. Changes in the (111) peak intensity upon field cycling in the $\pm[1\bar{1}0]$ direction after field cooling to 78 K in +14 kOe along the $[110]$ direction. The triangles (Δ) refer to the $[\text{Fe}_3\text{O}_4(100\text{ Å})/\text{CoO}(30\text{ Å})]_{50}$ and the squares (\square) to the $[\text{Fe}_3\text{O}_4(100\text{ Å})/\text{CoO}(100\text{ Å})]_{50}$ superlattices. The numbers and arrows refer to the order and direction of the field cycling. Solid lines are guides to the eye.

the antiferromagnet is essential to the effect. In particular, the observed perpendicular coupling between the antiferromagnetic CoO and ferrimagnetic Fe_3O_4 moments has been predicted previously by Hinchey and Mills²³ and connected to exchange-biasing more recently by Koon.¹¹ The coupling contrasts with most models of exchange-biasing which assume that the antiferromagnet always couples collinearly with the ferromagnet.⁷⁻¹⁰

Upon field cycling after field cooling in the $[1\bar{1}0]$ direction, we also observe some changes in the (111) peak intensity, as shown in Fig. 6. While field cooling in 14 kOe in the $[110]$ direction drives CoO spins out of the (111) domain (Fig. 4), the AFM spin structure is not completely frozen for both samples (Fig. 6). The partial return of the AFM spins into the (111) domain occurs at field values which are similar in magnitude to the coercive fields of the two samples [$H_c \sim 6000 \pm 100$ Oe for $\text{Fe}_3\text{O}_4(100\text{ Å})/\text{CoO}(30\text{ Å})$ and $\sim 3200 \pm 100$ Oe for $\text{Fe}_3\text{O}_4(100\text{ Å})/\text{CoO}(100\text{ Å})$ at 78 K]. As evident in Fig. 6, the $[\text{Fe}_3\text{O}_4(100\text{ Å})/\text{CoO}(100\text{ Å})]_{50}$ superlattice shows less recovery upon field cycling than the $[\text{Fe}_3\text{O}_4(100\text{ Å})/\text{CoO}(30\text{ Å})]_{50}$ sample and is hence more effectively “frozen” into a spin configuration. We note that in contrast to the 30 Å sample, for the 100 Å CoO superlattice, memory of the field cooled direction is retained upon heating and cooling above the AFM ordering temperature, indicating again the coupling to the Fe_3O_4 layers. To the degree to which this AFM response tracks the biasing, these differences are also consistent with the larger exchange-biasing fields and higher temperatures for the onset of biasing for the $[\text{Fe}_3\text{O}_4(100\text{ Å})/\text{CoO}(100\text{ Å})]_{50}$ sample.^{5,20}

However, the domain formation in these $\text{Fe}_3\text{O}_4/\text{CoO}$ superlattices is more subtle than that proposed by many of these models. Figure 7 shows the full widths at half maximum for the narrow CoO (111) reflection in remanence after field cooling in different directions within the sample growth plane. For both samples the widths for zero field cooling match within error those obtained after field cooling in the

FIG. 7. The full width at half maximum (FWHM) for the (111) CoO contributions scanned along the $[001]$ direction after cooling to 78 K in a 14 kOe field applied in different directions within the sample growth plane. The triangles (Δ) refer to the $[\text{Fe}_3\text{O}_4(100\text{ Å})/\text{CoO}(30\text{ Å})]_{50}$ and the squares (\blacksquare) to the $[\text{Fe}_3\text{O}_4(100\text{ Å})/\text{CoO}(100\text{ Å})]_{50}$ superlattices. The dashed line indicates the instrumental resolution limit. Lines between points are a guide to the eye.

$[110]$ direction. The larger errors associated with the widths for the $[1\bar{1}0]$ orientation reflect the decrease in CoO (111) intensity for these scans. After deconvolution with the instrumental resolution, the FWHM is inversely proportional to the AFM domain size along the growth axis direction. For the $\text{Fe}_3\text{O}_4(100\text{ Å})/\text{CoO}(30\text{ Å})$ sample, the average coherence length in the growth axis direction varies from $\sim 310 \pm 20$ Å for field cooling in the unpreferred $[1\bar{1}0]$ direction to $\sim 700 \pm 100$ Å for field cooling in the preferred $[110]$ direction. Field cooling thus leads to changes in the average domain size. However, in the case of the 100 Å sample, the widths are nearly resolution limited for all field directions with growth axis coherence lengths of greater than 800 Å. Thus, in both samples, domain walls do not occur at every superlattice interface. Scanning the (111) reflection along the $[110]$ direction in the growth plane, we find similarly large domain sizes across the sample plane.

In addition, upon field cycling, we observe changes in the average domain size of less than a few percent for the $[\text{Fe}_3\text{O}_4(100\text{ Å})/\text{CoO}(100\text{ Å})]_{50}$ sample which has larger exchange-biasing fields.^{5,20} This contrasts with most recent models of exchange biasing in that we do not observe domain walls forming in the antiferromagnet near each $\text{Fe}_3\text{O}_4/\text{CoO}$ interface upon field reversal. However, small twists or incomplete domain walls may form in the antiferromagnet which are not within the sensitivity of our measurement technique. Alternatively, the ferrimagnetic Fe_3O_4 may exhibit domain wall formation upon field cycling. In $\text{Fe}_3\text{O}_4/\text{NiO}$ multilayers, polarized neutron reflectivity experiments showed different magnetization depth profiles for the Fe_3O_4 layers before and after field reversal, suggesting such domain wall formation.²⁴ Further experiments are underway to explore this possibility for these $\text{Fe}_3\text{O}_4/\text{CoO}$ superlattices.

IV. SUMMARY/CONCLUSION

We have demonstrated the complex nature of the AFM spin structure in $\text{Fe}_3\text{O}_4/\text{CoO}$ superlattices. The spin arrangement of the CoO is influenced by both growth constraints

and a preferred perpendicular coupling to the net Fe_3O_4 moments. In general, the CoO domains are long range and extend coherently across intervening Fe_3O_4 layers. Upon field cooling, the AFM spins "freeze" into large domains which do not change size substantially upon field cycling. These results illustrate the importance of the details of the AFM spin structure in exchange-biased systems.

Role of interfacial uncompensated antiferromagnetic spins in unidirectional anisotropy in $\text{Ni}_{81}\text{Fe}_{19}/\text{CoO}$ bilayers (invited)

The uncompensated spins on the surfaces of antiferromagnetic CoO films exhibit a thermoremanent magnetization after field cooling from $T > T_N$ that has the same temperature dependence as the exchange field of $\text{Ni}_{81}\text{Fe}_{19}/\text{CoO}$ bilayers after field cooling. This suggests that these interfacial uncompensated spins are responsible for unidirectional anisotropy. A model based on a calculation of the density of these interfacial uncompensated spins predicts the correct magnitude of the exchange field, as well as the observed inverse dependence on average interfacial grain size.

I. INTRODUCTION

Exchange anisotropy¹ refers to the exchange interactions at an interface between ferromagnetic (FM) and antiferromagnetic (AFM) materials. Cooling a FM/AFM thin film bilayer from $T_C(\text{FM}) > T > T_N(\text{AFM})$ in a saturating magnetic field produces a unidirectional anisotropy that is manifested as a $\sin \theta$ component in the torque curve and a hysteresis loop displaced along the field axis. The loop shift is called the exchange field H_E . Recently, the technological application of AFM thin films to bias magnetoresistive devices² important to the magnetic recording industry has revived the interest in exchange anisotropy. Despite extensive experimental and theoretical investigations in the past 40 years, the basic details of the mechanism of this phenomenon remained unclear.

Assuming Heisenberg exchange across an epitaxial atomically smooth FM/AFM interface,

$$H_E = \frac{J_{\text{ex}} S_{\text{FM}} S_{\text{AFM}}}{a^2 M_{\text{FM}} t_{\text{FM}}}, \quad (1)$$

where J_{ex} is the exchange parameter, S_{FM} and S_{AFM} are the spins of the interfacial atoms, a is the cubic lattice parameter, and M_{FM} and t_{FM} are the magnetization and thickness of the FM layer, respectively. Observed exchange fields, however, are typically less than a few percent of the values predicted by this idealized model. A quantitatively satisfactory model for a specific exchange coupled system has not been reported until recently.³

Our measurements of thermoremanent magnetization (TRM) in CoO/MgO multilayers show that the spins responsible for this moment are interfacial and constitute $\sim 1\%$ of the spins in a monoatomic layer of CoO. The TRM exhibited the same features and temperature dependence as the ex-

change field of $\text{Ni}_{81}\text{Fe}_{19}/\text{CoO}$ bilayers. Since the TRM originates from the uncompensated interfacial AFM spins, they appear to be the spins responsible for unidirectional anisotropy. A model is presented which predicts the observed exchange field. It is based on a calculation of the density of interfacial uncompensated spins, and accounts for grain size, orientation, and interfacial roughness.

II. EXPERIMENTAL PROCEDURES

CoO has a Néel temperature, $T_N = 293$ K. The AFM ordering is characterized by FM aligned (111) planes with adjacent antiparallel (111) planes. The AFM alignment results from the superexchange coupling of the cobalt cation atoms via the p orbitals of the oxygen atoms. CoO/MgO multilayers were used to determine the magnetic properties of uncoupled CoO films since MgO is nonmagnetic. CoO and MgO share the fcc NaCl structure with bulk cubic lattice parameters which differ by only 1.1%. The structural similarity permits interlayer coherent growth. A series of $\text{CoO}(t_{\text{CoO}} \text{ \AA})/\text{MgO}(t_{\text{MgO}} \text{ \AA})$ multilayers were deposited with CoO thicknesses t_{CoO} ranging from 16 to 103 Å, and MgO thicknesses $t_{\text{MgO}} \sim 20$ Å. The structural characterization and heat capacity measurements of these multilayers are discussed in detail elsewhere.⁴ Thin film bilayers of CoO and permalloy ($\text{Ni}_{81}\text{Fe}_{19}$) were used to determine the role of AFM thickness on the interfacial exchange properties. A series of films was deposited with CoO thicknesses ranging from 100 to 3000 Å; the permalloy layer thickness was fixed at 300 Å. An Ag capping layer was deposited as an oxidation barrier.

The CoO⁵ and MgO films were reactively sputtered from a metal target. The permalloy was deposited by dc sputtering from an alloy target. The substrates were backed by Alnico magnets to apply a bias field during deposition to induce an easy axis in the permalloy. The films were deposited at 373 K with a rotating substrate table (~ 0.6 Hz) heated by a quartz lamp. The deposition rates were ~ 27 Å/min for the oxides and ~ 15 Å/min for the permalloy. Film thicknesses

FIG. 1. FC and ZFC moment densities vs temperature of the $[\text{CoO}(103 \text{ Å})/\text{MgO}(30 \text{ Å})]_{15}$ multilayer.

were established from rate checks. The substrates were Si(100) wafers with a native amorphous oxide layer ($\sim 30 \text{ Å}$). The films were polycrystalline as determined by x-ray diffraction and transmission electron microscopy (TEM). No evidence for any phase other than CoO was detected. The cubic lattice parameter derived from the (111) peak position is 4.27 Å which is slightly expanded (0.2%) from the bulk parameter (4.260 Å).

Magnetic measurements of the CoO/MgO multilayers and permalloy/CoO bilayer films were taken using a superconducting quantum interference device (SQUID) magnetometer. From a series of hysteresis loops measured at temperatures ranging from 10 to 320 K, the temperature dependences of the exchange fields were obtained for field cooled (FC) permalloy/CoO bilayer films. The permalloy easy axis (induced by the Alnico magnet) was aligned parallel to the measurement field.

III. RESULTS

The CoO/MgO multilayers were cooled from 350 to 10 K in zero field (ZFC) and in $+10 \text{ kOe}$ (FC). Magnetization measurements were made in a 100 Oe field. Field cooling resulted in a stable magnetization—i.e., a TRM. Figure 1 shows the FC and ZFC measurements for the $[\text{CoO}(103 \text{ Å})/\text{MgO}(30 \text{ Å})]_{15}$ multilayer. The interfacial TRM density exhibits two features: (i) an intermediate temperature region ($200 \text{ K} \geq T \geq 50 \text{ K}$) where the magnetization is independent of temperature (a “plateau”) and (ii) a low temperature increase ($T \leq 50 \text{ K}$). The magnitudes of these two features scale closely with the number of CoO layers and have no dependence on the net CoO thickness in the multilayers. Therefore the uncompensated moment of both features is an interfacial effect and not a bulk effect. Neutron data⁶ give $3.8 \mu_B$ for the magnetic moment of Co^{2+} in CoO. Thus the measured interfacial uncompensated moment represents $\sim 1\%$ of the spins in a monoatomic layer of CoO.

If the CoO/MgO multilayer is field cooled to 100 K and then zero field cooled from 100 to 10 K, the low temperature increase feature is absent from the TRM. Hence, the spins responsible for the low temperature increase require a moderate cooling field below 100 K to align them and will be referred to as the low freezing temperature (LFT) spins. For $T < 100 \text{ K}$, we observed relaxation and hysteresis. The LFT magnetization and irreversibility disappear above 100 K which is considerably lower than T_N , so we infer that the LFT spins are weakly coupled to the spins in the core of the

FIG. 2. Temperature dependence of H_E for permalloy (300 Å)/CoO bilayers with CoO thicknesses of 100–3000 Å.

CoO layers. These spins may be a small fraction of surface spins that are frustrated. Similar magnetic behavior was observed in disordered surface spins in NiFe_2O_4 nanoparticles⁷ and in isolated spin clusters in powders of randomly diluted fcc $\text{Co}_x\text{Mg}_{1-x}\text{O}$.⁸

In Fig. 1, the bifurcation of the FC and ZFC susceptibilities occurs at $295 \pm 5 \text{ K}$ (the bulk T_N of CoO). This suggests that the spins responsible for the plateau feature are magnetically coupled to the spins in the core of the CoO layers. For $100 < T < 200 \text{ K}$, the spins responsible for the plateau have anisotropy fields much larger than the LFT spins since (i) no magnetization reversal was observed in fields as large as -55 kOe and (ii) the $M-H$ loops exhibited a vertical displacement along the moment axis equal to the contribution due to the TRM. The TRM temperature dependence (for $T > 50 \text{ K}$) was similar to the temperature dependence of the sublattice magnetization for CoO as determined by neutron diffraction.⁹ This correlation further suggests a strong coupling of these interfacial spins to the core spins of the CoO film.

The permalloy/CoO bilayers were cooled from 350 K ($> T_N + 50 \text{ K}$) to 10 K in a $+10 \text{ kOe}$ field. Figure 2 shows $H_E(T)$ for some of the CoO thicknesses. $H_E(T)$ of permalloy/CoO films exhibit the plateau and low temperature increase features in identical temperature regions as the TRM of the CoO/MgO multilayers. In Fig. 3, the TRM of the $[\text{CoO}(103 \text{ Å})/\text{MgO}(30 \text{ Å})]_{15}$ multilayer and the $H_E(T)$ of the permalloy/CoO(100 Å) bilayer have been normalized at 70 K. The curves overlap at all temperatures except for the lowest temperature region $T < 50 \text{ K}$. Due to the distribution of lower anisotropy fields exhibited by the LFT spins, only a

FIG. 3. $H_E(T)$ (○) of the permalloy/CoO(100 Å) bilayer and the TRM (●) of the $[\text{CoO}(103 \text{ Å})/\text{MgO}(30 \text{ Å})]_{15}$ multilayer normalized at 70 K. The overlap for $T > 50 \text{ K}$ strongly suggests that the interfacial uncompensated spins responsible for the TRM plays an important role in the exchange field mechanism.

FIG. 4. Linear relationship between the plateau value of $H_E(T=50\text{ K})$ of the permalloy/CoO bilayers and the inverse of the CoO crystallite diameter.

small fraction of the LFT spins have sufficient anisotropy to effectively pin the permalloy layer. The correlation above 50 K strongly suggests that the interfacial uncompensated spins which are responsible for the TRM play an important role in the exchange field mechanism. The correlation also suggests that the temperature dependence of H_E is consistent with strong *net* unidirectional interfacial Heisenberg exchange that is proportional to the spin density of the uncompensated interfacial AFM spins. This proportionality, however, will only be observed for AFM grains with high magnetocrystalline anisotropy energy. This condition is not likely to be satisfied (i) in lower anisotropy AFM materials such as NiO and (ii) in small AFM grains since the magnetic energy scales with the grain volume. The observation that $\sim 1\%$ of the interfacial AFM spins are uncompensated is consistent with measured permalloy/CoO exchange fields of $\sim 1\%$ of the interfacial Heisenberg exchange model [Eq. (1)].

The H_E dependence with the CoO thickness suggests a structural origin for the density of uncompensated spins. Cross-sectional TEM showed a columnar structure for all thicknesses. The sizes of the CoO crystallites at the permalloy/CoO interface were examined by TEM plan views of CoO films without any capping layers. The average CoO crystallite diameter for thicknesses of 100, 500, 1000, and 3000 Å were determined by an analysis of the dark and bright field images. Figure 4 shows the linear relationship between $H_E(50\text{ K})$, which is representative of the plateau value, and the inverse of the CoO crystallite diameter.

IV. MODELING

The correlation between the temperature dependence of the TRM of the CoO/MgO multilayers and the exchange field of the permalloy/CoO bilayers suggests a direct relationship between the interfacial density of uncompensated spins and the strength of the exchange field. We present a model for H_E which demonstrates its connection with the interfacial density of uncompensated spins, and predicts the inverse relationship between H_E and the grain diameter. We assume that each CoO crystallite is a single AFM domain. We define the normal to the FM aligned (111)-type spin plane as $\hat{\mathbf{p}}$, and define the probability of finding a crystallite with that orientation at the AFM film surface as $f(\hat{\mathbf{p}})d\Omega_{\hat{\mathbf{p}}}$. We define the easy axis (known to be near the tetragonal axis in bulk CoO⁶) for a crystallite as $\hat{\mathbf{e}}$, and the probability of finding a crystallite with that easy axis as $g(\hat{\mathbf{e}})d\Omega_{\hat{\mathbf{e}}}$ (the sign of $\hat{\mathbf{e}}$ will be specified below). The FM aligned spin planes

FIG. 5. Schematic of interface cross section. Film normal is $\hat{\mathbf{n}}$, $\hat{\mathbf{p}}$ is the normal to the parallel spin plane (111) of the AFM, and $\hat{\mathbf{e}}$ is the AFM spin axis (in this case $N_{\text{rows}}=4$).

will intersect the interface in a series of atomic steps with spacing $d_{111}(1-(\hat{\mathbf{n}}\cdot\hat{\mathbf{p}})^2)^{-1/2} (=d_{111}/\sin\theta)$, where $d_{111}(=a\sqrt{3}/3=0.577a)$ is the spacing of (111) planes, and $\hat{\mathbf{n}}$ is the film normal, as indicated in Fig. 5. The interfacial layer of spins of each crystallite will consist of alternate rows of antiparallel spins pointing in the $\pm\hat{\mathbf{e}}$ directions. If $\hat{\mathbf{p}}$ is close to $\hat{\mathbf{n}}$, there may be two or more rows of parallel spins from each (111) spin plane at the interface. The number of adjacent rows of parallel spins may be estimated as

$$N_{\text{rows}} = \text{trunc} \left\{ \frac{d_{111}}{d_{110}} [1 - (\hat{\mathbf{n}}\cdot\hat{\mathbf{p}})^2]^{-1/2} \right\}, \quad (2)$$

where “trunc” gives the largest integer less than the argument and d_{110} represents the in-plane spacing. The interfacial exchange energy for crystallite i is

$$U_i = - \sum_{j=1}^N J_{\text{ex}} \mathbf{S}_{\text{FM},j} \cdot \mathbf{S}_{\text{AFM},j}.$$

If the ferromagnetic layer is in a single domain state,

$$\begin{aligned} U_i &= -\mathbf{S}_{\text{FM}} \cdot \left[\sum_{j=1}^N J_{\text{ex}} \mathbf{S}_{\text{AFM},j} \right] \\ &= -\mathbf{S}_{\text{FM}} \cdot [J_{\text{ex}}(N_{+,i} - N_{-,i})\mathbf{S}_{\text{AFM}}\hat{\mathbf{e}}], \end{aligned}$$

where N_{\pm} is the number of interfacial spins pointing in the $\pm\hat{\mathbf{e}}$ direction, and we define the sign of $\hat{\mathbf{e}}$ such that $J_{\text{ex}}(N_{+,i} - N_{-,i}) \equiv J_{\text{ex}}\Delta N_i$ is positive. As indicated in Fig. 6, if the AFM film is cooled below T_N in zero field, the uncompensated moment of the AFM domains are randomly oriented but collinear with the Néel axes of the AFM grains. If the AFM film is field cooled below T_N , the uncompensated moment of the AFM domain will orient itself such that $+\hat{\mathbf{e}}$ has a component in the direction of the adjacent FM spins (i.e., $\hat{\mathbf{H}}_{\text{cool}}$). Therefore

$$U_i^{\text{FC}} = -|J_{\text{ex}}|S_{\text{AFM}}S_{\text{FM}}\Delta N_i|\hat{\mathbf{e}}\cdot\hat{\mathbf{H}}_{\text{cool}}|.$$

The total interfacial energy is then

$$\begin{aligned} U_{\text{tot}}^{\text{FC}} &= -|J_{\text{ex}}|S_{\text{AFM}}S_{\text{FM}}N_c \left[\int d\Omega_{\hat{\mathbf{p}}} f(\hat{\mathbf{p}})\Delta N_i \right] \\ &\quad \times \left[\int d\Omega_{\hat{\mathbf{e}}} g(\hat{\mathbf{e}})|\hat{\mathbf{e}}\cdot\hat{\mathbf{H}}_{\text{cool}}| \right], \end{aligned}$$

FIG. 6. Schematic of uncompensated spin moment of uniaxial AFM grains. The uncompensated AFM spins are collinear with the Néel axes of the core of the AFM grains. The uncompensated AFM moments are randomly aligned in the zero field cooled case; whereas in the field cooled case, the uncompensated AFM moments are aligned along the uniaxial direction with a component in the cooling field direction.

where $N_c = \text{area}/L^2 = \text{total number of crystallites at the interface}$. If we assume that the AFM spins are frozen below T_N , and that $g(\hat{\mathbf{e}})$ is azimuthally symmetric, we find that the interfacial energy as a function of $\hat{\mathbf{S}}_{\text{FM}}$ is

$$\frac{U_{\text{tot}}^{\text{FC}}(\hat{\mathbf{S}}_{\text{FM}})}{\text{area}} = -(1/L^2)|J_{\text{ex}}|S_{\text{AFM}}S_{\text{FM}}(\hat{\mathbf{H}}_{\text{cool}} \cdot \hat{\mathbf{S}}_{\text{FM}}) \times \left[\int d\Omega_{\hat{\mathbf{p}}} f(\hat{\mathbf{p}}) \Delta N_i \right] \times \left[\int d\Omega_{\hat{\mathbf{e}}} g(\hat{\mathbf{e}}) |\hat{\mathbf{e}} \cdot \hat{\mathbf{H}}_{\text{cool}}| \right]. \quad (3)$$

Finally, following Malozemoff,¹⁰ we have

$$H_E = \frac{[U_{\text{tot}}^{\text{FC}}(-\hat{\mathbf{S}}_{\text{FM}}) - U_{\text{tot}}^{\text{FC}}(\hat{\mathbf{S}}_{\text{FM}})]/\text{area}}{2M_{\text{FM}}t_{\text{FM}}},$$

where M_{FM} and t_{FM} are the magnetization and thickness of the FM layer.

To compute the first integral in Eq. (3), we numerically calculated the average number of uncompensated spins for elliptical crystallites as a function of N_{rows} , which is related to the orientation $\hat{\mathbf{p}}$ by Eq. (2). We incorporated interfacial roughness as specified by the average lateral dimension of interfacial topographic features. We first mapped the interfacial plane onto a square lattice for computational convenience (this mapping slightly changes the shape of the model crystallites, but this is not significant). As shown in Fig. 7(a), the interfacial plane consists of a periodic pattern of N_{rows} rows of spins in the $+\hat{\mathbf{e}}$ direction, followed by N_{rows} rows of spins in the $-\hat{\mathbf{e}}$ direction. To simulate roughness, we superimposed elliptical “islands” of monoatomic thickness on the spin map. Figure 7(b) depicts the effect of adding one atomic layer as reversing the direction of the spin at each site covered by the island, since successive layers of CoO spins have opposite direction. The major axis of these islands was kept fixed (denoted “feature diameter”), while the position, orientation of the major axes, and aspect ratio (from 1:1 to 1:1.5) were varied. Islands were superimposed sequentially, allow-

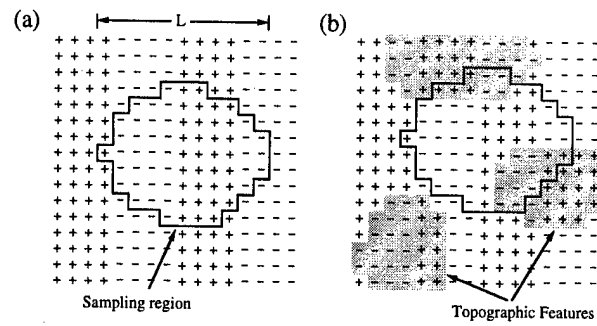

FIG. 7. Topographical representation of the interfacial plane. (a) Periodic pattern of $N_{\text{rows}} = 4$ (as in Fig. 5) with a sample region representing a model crystallite. (b) Elliptical islands of a monoatomic layer thickness were superimposed on the spin map to simulate roughness. Note that adding one atomic layer reverses the direction of the underlying spin.

ing overlap between them, until the total area of the islands equaled the total area of the spin map. Figure 8 is a representative topographical map containing overlapping islands with a feature diameter of 20 lattice parameters and coverage equal to the total area of the map. The varying shades of gray represent the degree of interfacial elevation above the base spin pattern consisting of a periodic pattern of N_{rows} rows of antiparallel spins [see Fig. 7(a)]. To compute the number of uncompensated spins for a model crystallite, ΔN_i , we simply added the total number of spins in each direction within an elliptical region, having major axis equal to L , on the spin map. We created a spin map which was several times larger than L , so a statistical average could be taken by varying the position, orientation of the major axis, and aspect ratio of the model crystallite (similar to the above procedure for generating roughness). Averages were taken by computing ΔN_i for 10^6 model crystallites. Although the base layer of the spin maps represents fully compensated spin planes (excluding perfect $\langle 111 \rangle$ orientation), the uncompensated moment originates from the finite dimensions imposed by the boundaries of the model crystallites and the density of roughness terraces.

The results of these calculations are summarized as follows: (1) a perfectly regular interface, with equally spaced

FIG. 8. Topographical map containing overlapping islands. The islands have a feature diameter of 20 lattice parameters and coverage equal to the total area of the map. The legend correlates the different shades of gray with the height of interfacial elevation above the base spin pattern [see Fig. 7(a)].

FIG. 9. Calculated values of the prefactor α and the exponent in power-law fits of $\langle \Delta N \rangle$ vs feature diameter and N_{rows} . $N_{\text{rows}}=1$ corresponds to $\theta > 24.1^\circ$ and $N_{\text{rows}}=14$ corresponds to $3.3^\circ > \theta > 3.1^\circ$. Prefactor α is weighted based on equal population of domains with the four different (111)-type parallel spin planes.

atomic terraces, results in $\langle \Delta N \rangle = \alpha(L/d_{110})^{0.5}$, (2) the addition of roughness results in $\langle \Delta N \rangle \approx \alpha(L/d_{110})^{0.90 \sim 1.04}$, (3) for small values of feature diameter $\langle \Delta N \rangle = 0.6(L/d_{110})$, independent of N_{rows} , and (4) the prefactor α increases as N_{rows} increases. These results are shown in Fig. 9. Since the result of Eq. (3) is proportional to $\langle \Delta N \rangle / L^2$, the rough case gives $H_E \sim L^{-1}$, in agreement with the experimental results of Fig. 4.

As an example, we calculate H_E for the 100 Å thick sample as follows. Recent work by the authors suggests,¹¹ via a mean field analysis of exchange coupled bilayers having different FM layers, that the interfacial exchange is a direct exchange between the metal ions. Following this approach, we estimate that the constant $J_{\text{ex}} S_{\text{AFM}} S_{\text{FM}} = \bar{T}_C / 8$

$= 143$ K, where \bar{T}_C is the Curie temperature of the interfacial alloy $(\text{Ni}_{81}\text{Fe}_{19})_{0.5}\text{Co}_{0.5}$.¹² X-ray diffraction rocking curves of the CoO (222) peak are nearly flat, indicating the absence of a strong crystallographic texture. Therefore, we assume uniform distributions of crystallite orientations (i.e., $f(\hat{\mathbf{p}})$ and $g(\hat{\mathbf{e}})$ are constant). With these parameters, we calculate exchange fields of 107, 80, 63, 50, 40, and 31 Oe for topographic feature diameters of 12, 30, 60, 120, 240, and 480 Å, respectively. The experimental result of 48 Oe is consistent with a topographic feature diameter of approximately 120 Å. This result is consistent with interfacial roughness of only a few “extra” atomic steps across the face of each crystallite.

V. SUMMARY

We measured the interfacial uncompensated moment on an AFM surface as a TRM of a field-cooled CoO/MgO multilayer. The temperature dependence of the interfacial uncompensated AFM moment parallels that of the exchange field of permalloy/CoO bilayers. A model for unidirectional anisotropy correctly predicts the inverse dependence of the uncompensated spins on grain size and the correct magnitude of H_E .

Two measurement techniques, both relying on reversible rotations of the magnetization, have been used to determine the magnitude of the interfacial exchange energy (IEE) between ferromagnetic and antiferromagnetic (F/AF) layers. One technique is to use the anisotropic magnetoresistance to determine rotations of the magnetization away from the unidirectional easy axis, where the rotation is accomplished by applying external magnetic fields less than the effective F/AF exchange field. The second technique uses measurements of the ac susceptibility as a function of the angle between the ac field and the unidirectional exchange field. Both of the reversible process techniques result in values of the IEE larger (by as much as a factor of 10 in Co/CoO bilayers) than the traditional irreversible technique of measuring a shift in the hysteresis loop. The ac susceptibility technique was also used to measure one Fe/FeF₂ bilayer. For this sample, the IEE values obtained by reversible and irreversible methods are equivalent. © 1998 American Institute of Physics. [S0021-8979(98)53611-0]

Meikeljohn and Bean^{1,2} discovered an interfacial exchange energy between ferromagnets and antiferromagnets which could generate a unidirectional easy axis for the ferromagnet. This unidirectional anisotropy is generated by field cooling the system from above the Néel temperature to below. Although this discovery occurred almost 40 years ago, we have not yet developed a fundamental understanding of this phenomena. Briefly, the first model to attempt to describe the observed behavior assumed that the ferromagnet was uniformly coupled to one sublattice of the antiferromagnet. However simple calculations with this model gave interfacial exchange energies (IEE) approximately a factor of 100 times larger than the values reported by experiments. Due to this discrepancy alternate models of the IEE were developed, however, none of these appear to completely explain the observed data.³ Our lack of understanding of the IEE may arise, not from a lack of theoretical understanding but instead from an inherent error in the experimental determination of the IEE.

Historically the experimental determinations of the IEE phenomenon have been almost exclusively from measurements of the shift or offset in the hysteresis loops of direct exchange coupled ferromagnet/antiferromagnet systems. This measurement technique is intrinsically irreversible, and is actually a measure of the nucleation and propagation of domain walls during the reversal process. As such its relation to the exchange bias energy is not necessarily simple. An-

other difficulty with this technique is the common observation that cycling through multiple hysteresis loops results in decreasing values of the shift in the loops.

We have recently used two different experimental techniques which involve only reversible rotations of the magnetization to determine the interfacial exchange energy in Co/CoO bilayers.^{4,5} These measurements produce values of the energy which are consistently larger than those determined by hysteresis loop measures on the same films. Although these reversible measures are larger than the irreversible measures, they are still less than the original predictions based on a direct coupling between the ferromagnet surface and a single sublattice of the antiferromagnet.

In what follows, we will briefly summarize both the techniques and results from the above mentioned two works. In both, the samples consisted of sputtered Co films (thicknesses from 2 to 30 nm) with a native oxide coating formed upon removal from the sputtering system (thus forming bilayers of Co/CoO). As the CoO has a Néel temperature slightly below room temperature, the exchange bias direction was easily controlled by field cooling the bilayers from room temperature to low temperature. In addition to the Co/CoO work, we will mention one study of another system, Fe exchange coupled to epitaxially grown antiferromagnetic FeF₂. At the end are a series of conclusions which can be drawn from this work.

Our first reversible measurement of the IEE relied on the anisotropic magnetoresistance (AMR) to determine the direction of the magnetization in thin films.⁴ In this work, the resistance of Co/CoO bilayers were measured as a function of the angle between an in-plane applied magnetic field and the exchange bias direction. The applied magnetic fields

^{a)}Electronic mail: dand@physics.spa.umn.edu

were as large as 40% of the effective field of the IEE. Using the relationship for the resistance of a ferromagnet with an angle between the current and the magnetization,⁶ we were able to fit the resistance of the films as a function of the applied field direction with one adjustable parameter, the average exchange biasing energy. As shown in this work, the applied magnetic field could be rotated through a full 2π twice obtaining the same angle dependent resistance data indicating the reversible nature of the measurement technique.

In order to prove a difference between the reversible and irreversible measurements, the maximum possible value for the hysteresis loop measured exchange anisotropy was used, the value of the magnetic field when the magnetization reversed. Thus, this determination included half the width of the hysteresis loop in the shift, i.e., the reported values for the hysteresis loop determination of the exchange bias were the exchange bias field plus the coercivity (this was not clearly stated in this work). This is certainly an overestimate of the exchange bias but even so, it was still smaller than that determined by the reversible AMR technique. In general, when correcting for the coercivity, the AMR determined IEE was about a factor of 4 times larger than the hysteresis loop measurement for films on the order of 4 nm thick.

Another interesting feature found in this work was that the magnetization rotation through the ferromagnetic film was not uniform in the AMR or reversible measurements. Although this was not observed in the hysteresis measurement, it is rather obvious it should be present as shown in the following. The exchange pinning of the ferromagnet occurs at the interface between the Co and the CoO. In a thick Co film, say on the order of 10 nm or more, the spins at the free surface, opposite the interface, are only weakly pinned (the bias must propagate through the film via the direct exchange of the Co from one layer to the next). In this case if a magnetic field is applied at a large angle to the biasing direction, the spins on the free surface rotate towards the field more than those at the pinning interface. Thus, in progressing through the film thickness, the rotation varies from a maximum amount (on the free surface) to a minimum (at the pinning interface). This situation is not dissimilar to having a domain wall or a partial wall form through the thickness of the film.

The second reversible technique we used to measure the IEE was the ac susceptibility. In this case the ac susceptibility was measured as a function of the angle between the exchange bias direction and the ac magnetic field with ac magnetic fields as small as 0.1% of the effective exchange bias field. A simple understanding of how this was used to determine the IEE is to consider the analogy with the susceptibility of an antiferromagnet.⁷ The measured susceptibility of an antiferromagnet depends upon the orientation of the magnetic field to the spins in the sublattices, with the collinear susceptibility smaller than the perpendicular susceptibility. The difference between these susceptibilities is related to the exchange energy between the two sublattices.

The ac susceptibility measurements were performed as a function of temperature revealing a linear temperature dependence of the exchange biasing magnitude (the AMR study was performed only at 4 K). The results from this

second study were in agreement with the AMR study, in that this reversible measurement of the IEE was larger than that determined by the irreversible hysteresis loop technique. However, it found energies larger by as much as a factor of 10 than the hysteresis loop measurements (recall a factor of 4 was observed in the AMR studies). It is important to note that the two reversible studies were made on different sets of samples so it is not clear if this difference in the factor is due to the smaller field used in the ac susceptibility study or sample differences.

An interesting feature of note in the susceptibility study came from two Co samples of the same thickness. One was partially capped with Ag prior to oxidation to prevent the formation of the CoO over some fraction of the surface while the other did not have the oxide inhibiting Ag coating. Surprisingly, the hysteresis loop measurement of the sample with the partial Ag overcoat indicated an IEE larger than the sample with the full oxide. This was contradicted by the ac susceptibility measurements on the same two samples which indicated a reduction in the IEE for the sample with the smaller ferromagnetic antiferromagnetic interface area as one would expect. Although this comparison was between only these two samples, it does suggest that there may be difficulties in trying to determine even the systematics of the interfacial exchange energy by hysteresis loop measurements.

Another system we have recently investigated by the ac susceptibility method is Fe deposited on epitaxially grown FeF_2 .⁸ This system is rather unique for two reasons; it does not exhibit a decay or alteration of the ferromagnetic antiferromagnetic IEE upon repeated hysteresis loop cycles at low temperatures and the determination of the exchange energy from the loop shifts agree with that determined by the reversible techniques. That the loops are preserved upon repeated cycles is probably the result of two things. The crystalline anisotropy energy of the FeF_2 is high and the epitaxial growth with twinning results in the FeF_2 film being large single crystals. Thus the FeF_2 sublattice orientations are well fixed and the applied magnetic field and the exchange from the iron film is insufficient to reorient the sublattice orientations. This might be sufficient to assume the two techniques would give the same value for the IEE, however this means that either the energy and dynamics for domain wall formation (which is localized to the wall width) is identical to the uniform rotation of the magnetization at the interface, or the hysteresis loop reversal mechanism is not by wall formation but instead of coherent rotation.

In ending, a number of conclusions and questions can be drawn from these studies.

First, in general, reversible measurements of the interfacial exchange coupling energy are more accurate than measures relying on irreversible processes. A cautionary note however arises upon considering the anisotropy energy of the antiferromagnet. If the crystalline anisotropy or the crystallite size of the antiferromagnet is small compared to exchange bias energy, then pinning of the ferromagnet is not only by the interfacial exchange coupling but instead will be a mixture of the exchange energy and the anisotropy energy.

Thus in this case, even reversible measurements do not provide an accurate determination of the interfacial exchange energy.

Next, there is the question of what the hysteresis loop measures. The irreversible techniques are almost certainly measurements of some combination of domain wall nucleation energies in the ferromagnetic film where the lowest interfacial energy occurs and domain wall pinning. For this reason, even systematic studies of the IEE where grain size or some other parameter is varied is suspect unless their effect on the wall nucleation and pinning are well known.

It is interesting that the Fe/FeF₂ system reveals equivalent results for the IEE using both reversible and irreversible measures. This preliminary result is interesting for the following reasons. The robust nature of the loop shift upon repeated magnetic reversals may be an indicator when the hysteresis loop technique is accurate for determining the IEE. However, when the details are considered, it is surprising that the energetics of wall formation and propagation are the same as the as small rotations of the magnetization. However, as stated, only one sample was investigated and certainly more must be studied before any conclusions are drawn.

Finally there are the apparent differences in the measured values of the energy for the AMR (factor of 4 times

larger than the hysteresis determined value) and ac susceptibility (as much as a factor of 10 times larger) techniques. One possibility is this may be due to the differences in the field of measurement as the minimum ac susceptibility magnetic field is approximately 0.01 that of the AMR technique. However, it is important to note that these measurements were not performed on the same set of samples. This clearly warrants a study of the exchange bias energies determined by the ac susceptibility, AMR, and hysteresis loop techniques on the same samples.

Immobilization diffusion in R_2Fe_{17} nitrides

R. Skomski and S. Wirth^{a)}

Max-Planck-Institut für Mikrostrukturphysik, Weinberg 2, 06120 Halle, Germany

The diffusion of nitrogen in R_2Fe_{17} intermetallics is investigated by an approach which reconciles the solid-solution and immobilization theories of nitrogen diffusion. It turns out that two-sublattice diffusions may yield sharp concentration profiles but leave the phase structure of the nitride unchanged. Beside the reaction time and a local relaxation time there exists a global relaxation time which governs the smoothing of concentration gradients. Due to the large number of unknown energy parameters involved it is difficult to make quantitative predictions, but in general the diffusion behavior depends on factors such as the use of N_2 or NH_3 as a nitrogen source. © 1998 American Institute of Physics. [S0021-8979(98)42411-3]

I. INTRODUCTION

Since the discovery of interstitial permanent magnets such as $Sm_2Fe_{17}N_3$,¹ the diffusion of nitrogen and carbon in R_2Fe_{17} intermetallics has attracted much attention.²⁻¹² The knowledge of the diffusion mechanism is necessary to predict the extrinsic properties of the interstitial magnets. A particular problem is that soft regions associated with incomplete nitrogenation destroy coercivity by acting as nucleation centers, so that the nitrogen concentration in the material has to be homogeneous.^{2,3}

In recent years, there has been considerable controversy about the phase structure of interstitial nitrides. According to the solid-solution theory, the reaction of molecular nitrogen with Sm_2Fe_{17} yields homogeneous solid solutions $Sm_2Fe_{17}N_x$ with intermediate nitrogen contents.^{2,3,5,8,10,13} By contrast, the two-phase theory states that the nitrides $R_2Fe_{17}N_x$ are a mixture of nitrated ($x \approx 3$) and unnitrated ($x \approx 0$) phases without intermediate nitrogen contents.^{6,11,12} Figure 1 illustrates the difference between solid solutions and compounds.

It is important to note that phase segregation is caused by *attractive interactions* between interstitial atoms, whereas the on-site interaction between the interstitial atoms and the host lattice changes leaves the phase structure unchanged.^{8,10,14} In fact, phase transitions of gases in metals are caused by long-range elastic interactions, which yield a critical temperature T_0 below which phase segregation occurs. By contrast, electronic interactions in metals are short ranged and largely repulsive.^{8,10,14}

The nitrogen atoms diffuse inwards from the surface of the R_2Fe_{17} particles, which has given rise to the qualitative concept of core-shell diffusion.¹⁵ A key question is whether the nitrogen concentration profiles $0 \leq c(r,t) \leq 1$ of partly

nitrated particles are smooth or steplike (Fig. 2). The one-sublattice diffusion equation $\partial c / \partial t = D \nabla^2 c$, where $D = D_0 \times \exp(-E_a/k_B T)$, yields smooth nitrogen profiles.^{2,8,10} Based on this model, an activation energy $E_a = 133$ kJ/mole was obtained from thermopiezic measurements on Sm_2Fe_{17} in N_2 . Both this activation energy and the diffusion parameter $D_0 = 1.02$ mm²/s are typical for $2p$ atoms in transition metals.^{2,3,8,10} Note that experimental diffusion constants vary between from 59 to 163 kJ/mole.^{4,7,8,16}

In the two-phase regime the diffusion constant depends on c and T . The mean-field result $D = D_0 \exp(-E_a/k_B T) \times [1 - 4c(1-c)T_0/T]$ shows that there exist negative diffusion constants below T_0 , which describe the creation of sharp phase boundaries.¹⁰ Note the width of the “sharp” transition regions is as large as about $1 \mu m$,¹² which can hardly be interpreted as critical fluctuations in the vicinity of the unknown critical temperature T_0 .

Most of the evidence available for $Sm_2Fe_{17}N_x$ produced from N_2 gas favors a gas-solid solution at typical nitrogenation temperatures of about $500^\circ C$. In particular, intermediate lattice parameters have been observed by x-ray diffraction analysis,³ samples with intermediate nitrogen contents ex-

FIG. 2. Nitrogen concentration profiles for spherical particles: (solid line) ideal one-sublattice diffusion and (dotted line) sharp interface.

hibit intermediate Curie temperatures,⁵ homogenization of partly nitrated grains yields intermediate nitrogen concentrations,¹³ electron micrographs show smoothly varying nitrogen concentrations,⁹ and domain-size observations¹⁷ can be explained by intermediate anisotropy constants only.

However, in practice it is difficult to distinguish solid solutions from two-phase nitrides,^{10,18} and the solid-solution character of $R_2Fe_{17}N_x$ has been questioned by several authors.^{6,11,12} Zhang *et al.* have argued that nitrogen diffusion in R_2Fe_{17} compounds is realized by more than two sublattices of interstitial sites.^{11,12} Starting from the known crystal structure, they postulated the existence of trapping (t) and free (f) sites. It is assumed that the f -sites act as an easy diffusion pathway for the nitrogen atoms, which immobilize on the t sites. In the limit of ideal immobilization, where the on-site energy U_t goes to minus infinity, the immobilization mechanism yields sharp diffusion boundaries.¹⁹ However, this limit amounts to an infinite heat of reaction, whereas experimental reaction energies U_t are merely of order -57 kJ/mole.²

In this theoretical study, we investigate the possibility of immobilization diffusion and relate the diffusion behavior to the site and saddle-point energies of the nitrogen atoms. In particular, we answer the question whether immobilization diffusion leads to phase segregation.

II. IMMOBILIZATION DIFFUSION

As a rule, R_2Fe_{17} intermetallics containing light rare earths crystallize in the rhombohedral Th_2Zn_{17} structure, whereas heavy rare earths tend to form the hexagonal Th_2Ni_{17} structure. The two structures derive from the $CaCu_5$ structure but differ by the stacking of the $CaCu_5$ -type layers. In the rhombohedral structure, the majority of the nitrogen atoms occupies the large octahedral $9e$ sites (t sites), whereas the equilibrium occupancy of the $18g$ or $3b$ sites (f sites) is small.^{1,2,10,20} Since there are three t sites per formula unit, the nominal composition of the nitrides is often written as $R_2Fe_{17}N_3$.

FIG. 3. Schematic energy landscape of the two-sublattice diffusion model. Note that E_0 is not necessarily larger than E_f and E_t .

In the limit of strong immobilization, the nitrogen uptake is determined by the differential equation $dL/dt \approx D_f \langle c_f \rangle / \langle c_t \rangle L$, where L is the thickness of the fully nitrated shell and D_f is the diffusion constant of the f -type nitrogen atoms. The averages $\langle c_t \rangle \approx 1$ and $\langle c_f \rangle \ll 1$ are the equilibrium nitrogen concentrations on the respective sites. The solution of this equation, $L = \sqrt{2D_f \langle c_f \rangle t / c_0}$, is reminiscent of the diffusion length $L_0 = \sqrt{Dt}$ and yields the reaction time $t_R \approx R^2 / D \langle c_f \rangle$.

In reality, U_t is finite and we have to start from the two-sublattice diffusion equation

$$\frac{\partial c_t}{\partial t} = D_t \nabla^2 c_t - W_{ft} c_t + W_{tf} c_f, \quad (1a)$$

$$\frac{\partial c_f}{\partial t} = D_f \nabla^2 c_f - W_{tf} c_f + W_{ft} c_t, \quad (1b)$$

where the intrasublattice diffusion constants D_i ($i=f, t$) are

$$D_i = D_0 \exp\left(\frac{U_i}{k_B T} - \frac{E_i}{k_B T}\right). \quad (2)$$

The intersublattice transition rates $W_{ft} = W(t \rightarrow f)$ and $W_{tf} = W(f \rightarrow t)$ are given by

$$W_{ft} = \Gamma_0 \exp\left(\frac{U_t}{k_B T} - \frac{E_0}{k_B T}\right), \quad (3a)$$

$$W_{tf} = \Gamma_0 \exp\left(\frac{U_f}{k_B T} - \frac{E_0}{k_B T}\right). \quad (3b)$$

In Eqs. (1) and (2), U_f and U_t are the nitrogen on-site energies, E_f and E_t are intrasublattice saddle-point energies, and E_0 is the energy of the intersublattice saddle point connecting neighboring f and t sites (Fig. 3). In a fair approximation, $\Gamma_0 = D_0 / a_{\text{eff}}$, where $a_{\text{eff}} \approx 3 \text{ \AA}$ is an effective jumping distance.

Since Eq. (1) is difficult to solve, we use the approximate ansatz

$$c_i(x, t) = c_{i0} \exp(-t/\tau) \cos(2\pi x/L), \quad (4)$$

which transforms Eq. (1) into a quadratic secular equation. The diagonalization of the matrix yields two relaxation modes (Fig. 4). The local relaxation time t_L ,

$$t_L = \frac{a_{\text{eff}}^2}{D_0} \exp\left(\frac{E_0 - U_f}{k_B T}\right), \quad (5)$$

FIG. 4. Splitting of relaxation modes due to immobilization diffusion (schematic). Δc is the deviation from equilibrium.

describes transitions from the f sublattice to the t sublattice and is comparatively small. Note that the local character of t_L is seen from the absence of the "particle size" L in Eq. (5).

The global relaxation time

$$t_G = \frac{L^2}{4\pi^2} \frac{\exp(-U_i/k_B T)}{\exp(-E_i/k_B T) + \exp(-E_f/k_B T)} \quad (6)$$

describes the approach towards macroscopic equilibrium and equals the time necessary to homogenize an originally step-like concentration profile. For one-sublattice solid-solution diffusion $t_G \approx t_R$, whereas immobilization diffusion is characterized by $t_G > t_R$. Since the homogenization leads to smooth nitrogen concentration profiles, the existence of sharp boundaries during immobilization diffusion does not establish a separate nitride phase. By comparison, interatomic interaction yields sharp equilibrium phase boundaries below T_0 .^{2,3,8,10,14}

III. DISCUSSION AND CONCLUSIONS

Since Eq. (1) involves five energy values, it is not possible to predict the diffusion behavior from the known $\text{Sm}_2\text{Fe}_{17}\text{N}_x$ values U_i and $E_a = E_i - U_i$. Magnetic after effect measurements¹⁶ yield a third experimental value, $Q = E_0 - E_f/2 - E_i/2 = 62$ kJ/mole for $\text{Nd}_2\text{Fe}_{17}\text{N}_x$.

A possible explanation for the steplike profiles observed for $\text{Sm}_2\text{Fe}_{17}$ heated in ammonia is that the high effective nitrogen pressure associated with the presence of NH_3 enhances the concentration $\langle c_f \rangle$ and therefore reduces t_R .^{8,9,21} Note, however, that NMR experiments on $\text{Sm}_2\text{Fe}_{17}$ nitrided in ammonia show a large number of defects,^{8,22} which complicates the interpretation of the experimental results.

In general, we expect some dependence of the energy parameters on the rare earth's atomic number. A particularly difficult situation is found in intermetallics which may occur

in either of the 2:17 structures, such as Y_2Fe_{17} . Variable²³ nitrogen environments observed by NMR indicate a considerable volume fraction of intermediate material, which is contradictory to the absence of intermediate nitrogen concentrations in $\text{Y}_2\text{Fe}_{17}\text{N}_x$. This does not exclude, however, that $\text{Y}_2\text{Fe}_{17}\text{N}_x$ is more difficult to homogenize than $\text{Sm}_2\text{Fe}_{17}\text{N}_x$.

In conclusion, we have shown that intersublattice diffusion involving nonequivalent sites leads to local and global relaxation modes. In general, both relaxation times differ from the reaction time. Depending on the site and saddle-point energies involved, smooth or steplike nitrogen concentration profiles are obtained, but the phase structure of the nitride is not affected by immobilization.

A nearly perfect magnetic alignment of $R_2Fe_{17}N_x$ powders ($<20\text{ }\mu\text{m}$) with respect to the c axis was obtained by using the sample-rotation magnetic-alignment technique. The magnetization from 4.2 to 300 K was measured on the magnetically aligned samples by means of the sample-extraction method in a static field up to 23 T. The Fe-sublattice anisotropy was determined by analyzing the magnetization curves of $R_2Fe_{17}N_x$ with $R=Y, Ce, Gd$, and Lu . Compared to corresponding R_2Fe_{17} compounds, the Fe-sublattice anisotropy of $R_2Fe_{17}N_x$ is substantially lower. For $R_2Fe_{17}N_x$ with $R=Pr, Nd, Sm, Tb$, and Er , the magnetization curves in the $[001]$ direction show no anomaly whereas a first-order magnetization process (FOMP) was detected in corresponding R_2Fe_{17} compounds, suggesting that the FOMP transition in R_2Fe_{17} is suppressed upon nitrogeation.

I. INTRODUCTION AND MOTIVATION

The easy magnetization direction (EMD) of $R_2Fe_{17}N_x$ for all rare earths (R) except that for $R=Sm$ is within the basal plane. A detailed study of the magnetic anisotropy of these compounds is still lacking. This is because, on one hand, single crystals of $R_2Fe_{17}N_x$ are not possible to be grown by the conventional method since the compounds decompose above about 800 K. On the other hand, the powdered particles of $R_2Fe_{17}N_x$ compounds exhibit basal-plane anisotropy and can therefore not be well aligned magnetically by using the static-field-alignment technique. In the present investigation, a sample-rotation magnetic-alignment technique was used to align fine single-crystalline powder of $R_2Fe_{17}N_x$ compounds in an optimal way so that the magnetic anisotropy of the whole series of compounds can be systematically studied. This method has been applied by Wang *et al.*¹ to $Y_2Co_{14}B$ and Er_2Co_{17} , by Kou *et al.* to $Er_2Fe_{14}B^2$ and to the whole R_2Fe_{17} series,^{3,4} by Téllez-Blanco *et al.*⁵ to $Y_3(Fe,Ti)_{29}$, and by Zhang *et al.*⁶ to Sm_2Fe_{17} .

II. EXPERIMENTAL DETAILS

Polycrystalline ingots of R_2Fe_{17} compounds with $R=Y, Ce, Pr, Nd, Sm, Gd, Tb, Dy, Ho, Er, Tm$, and Lu were prepared by induction melting appropriate amounts of the constituent metals having a purity better than 99.99 wt %. X-ray diffraction was used to check the phase purity and to determine the lattice constants of the annealed samples, and also to determine the degree of magnetic alignment of the aligned samples. The $R_2Fe_{17}N_x$ compounds were obtained by flowing purified nitrogen gas N_2 over finely powdered R_2Fe_{17} ($<20\text{ }\mu\text{m}$) in a quartz tube at 773 K for 10 h. The particle size of R_2Fe_{17} is not expected to change during the nitrogeation process. It is therefore reasonable to assume that the $R_2Fe_{17}N_x$ powder particles have the same size distribution as the R_2Fe_{17} powder. The $R_2Fe_{17}N_x$ particles were

mixed with epoxy resin and embedded into a teflon tube of cylindrical shape. The teflon tube was connected with a motor that enables the tube to be spun in a static field of about 1 T with the cylinder axis perpendicular to the field direction until the epoxy resin has solidified. This process ensures that the basal planes, perpendicular to the c axis, are aligned parallel to each other and that the c axis will be parallel to the cylinder axis. The details including a schematic illustration of the sample-rotation magnetic-alignment method can be found in Ref. 3. X-ray diffraction performed on magnetically aligned samples with the sample surface parallel and perpendicular to the cylinder axis (i.e., to the c axis), indicates perfect magnetic alignment with respect to the c axis.

The magnetization parallel to the c axis, the magnetic hard direction for all $R_2Fe_{17}N_x$ compounds except for $R=Sm$, was measured from 5 to 300 K by means of the sample-extraction method in the 23 T resistive magnet at the Grenoble High Magnetic Field Laboratory. For calibration, the magnetization of the $R_2Fe_{17}N_x$ compounds was determined in a superconducting quantum interference device

FIG. 1. Temperature dependence of the anisotropy field of $R_2Fe_{17}N_x$ compounds with $R=Y, Ce$, and Gd . The data for Y_2Fe_{17} and Gd_2Fe_{17} , taken from Ref. 3, are presented for comparison.

FIG. 2. The magnetization measured on magnetically aligned $\text{Pr}_2\text{Fe}_{17}\text{N}_{2.7}$ with the field applied in the [001] direction, the magnetic hard direction. The magnetization data in the easy direction has been obtained in a SQUID magnetometer in fields up to 5 T on fine powder consisting of small single crystals ($<20\ \mu\text{m}$) which were loosely loaded in the sample holder. The data at 23 T was taken as the same as at 5 T with the purpose to demonstrate the magnetic anisotropy.

(SQUID) magnetometer in field strengths up to 5 T on finely powdered single crystallites ($<20\ \mu\text{m}$) which were loaded loosely in the sample holder so that they could be oriented by the applied field. During the measurements, the EMD of the single crystallites is always parallel to the field direction which ensures that the saturation magnetization is measured.

III. RESULTS AND DISCUSSION

X-ray diffraction shows that the $\text{R}_2\text{Fe}_{17}\text{N}_x$ compounds with $\text{R}=\text{Ce}$, Pr , Nd , and Sm have a rhombohedral structure, with $\text{R}=\text{Y}$, Ho , Er , Tm , and Lu a hexagonal structure and with $\text{R}=\text{Gd}$, Tb , Dy these two structures are coexisting. This is similar to their R_2Fe_{17} parent compounds. The Fe-sublattice anisotropy in $\text{R}_2\text{Fe}_{17}\text{N}_x$ compounds can be estimated from a study of compounds in which the R-sublattice

FIG. 3. The magnetization measured on magnetically aligned $\text{Nd}_2\text{Fe}_{17}\text{N}_{2.95}$ with the field in the [001] direction, the magnetic hard direction. The magnetization data in the easy direction has been obtained in a SQUID magnetometer in fields up to 5 T on fine powder consisting of small single crystals ($<20\ \mu\text{m}$) which were loaded loosely in the sample holder. The data at 23 T was taken as the same as at 5 T with the purpose to demonstrate the magnetic anisotropy.

FIG. 4. The magnetization measured on magnetically aligned $\text{Sm}_2\text{Fe}_{17}\text{N}_{2.9}$ with the measuring field applied perpendicular to the [001] direction. The magnetization data in the [001] direction has been obtained in a SQUID magnetometer in fields up to 5 T on fine powder consisting of small single crystals ($<20\ \mu\text{m}$) which were loaded loosely in the sample holder. The data at 23 T was taken as the same as at 5 T with the purpose to demonstrate the magnetic anisotropy.

anisotropy is absent. This is the case for $\text{R}=\text{Y}$, Gd , and Lu . Y and Lu are nonmagnetic, and Gd is an S-state R element which in principle does not contribute to the anisotropy in $\text{Gd}_2\text{Fe}_{17}\text{N}_x$. Due to the tetra-valent state Ce , the Fe-sublattice anisotropy can be also evaluated by studying $\text{Ce}_2\text{Fe}_{17}\text{N}_x$. Figure 1 shows the temperature dependence of the anisotropy field H_A of $\text{R}_2\text{Fe}_{17}\text{N}_x$ compounds with $\text{R}=\text{Y}$, Gd , and Ce , obtained by analyzing the magnetization curves. The values of H_A were determined to be the field where a singularity appears in the curve of d^2M/dH^2 versus H . This is basically the idea of the singular-point-detection (SPD) method which has been widely used to determine the anisotropy field directly on polycrystalline magnetic materials.⁷ The values of H_A of Y_2Fe_{17} and $\text{Gd}_2\text{Fe}_{17}$ obtained from a previous study³ are presented for comparison. It is evident that at low temperature the anisotropy field of $\text{Y}_2\text{Fe}_{17}\text{N}_x$ and $\text{Gd}_2\text{Fe}_{17}\text{N}_x$ is much lower than that of Y_2Fe_{17} and $\text{Gd}_2\text{Fe}_{17}$. For the Fe sublattice, the magnetic anisotropy energy E_a equals $0.5 H_A M_s$ where H_A is the anisotropy field and M_s the spontaneous magnetization. The M_s values of R_2Fe_{17} are only slightly changed upon nitrogenation. It can therefore be concluded that at low temperatures the Fe-sublattice anisotropy in $\text{R}_2\text{Fe}_{17}\text{N}_x$ compounds is lower than that in the corresponding R_2Fe_{17} compounds. Compared to the Fe-sublattice anisotropy, the R-sublattice anisotropy is, in most cases, dominating at low temperatures. The Sm-, Er-, and Tm-sublattice anisotropy favor an EMD parallel to the c axis both in R_2Fe_{17} and in $\text{R}_2\text{Fe}_{17}\text{N}_x$ compounds. $\text{Tm}_2\text{Fe}_{17}$ is the only compound in the whole R_2Fe_{17} series which shows a spin-reorientation transition at about 72 K.⁸ This transition is caused by competition between the planar Fe sublattice and the uniaxial Tm sublattice. Partly due to the lowering of the Fe-sublattice anisotropy in $\text{R}_2\text{Fe}_{17}\text{N}_x$ compounds, a spin-reorientation transition at 146 K is also induced in $\text{Er}_2\text{Fe}_{17}\text{N}_{3.0}$.⁹ Very exciting is that the $\text{Sm}_2\text{Fe}_{17}\text{N}_x$ becomes

easy-axis materials over the whole temperature range of magnetic ordering, which makes it a very promising candidate for permanent magnets fabrication.

In a previous study,⁴ a pronounced first-order magnetization process (FOMP) in $\text{Pr}_2\text{Fe}_{17}$ with the field applied in the [001] direction has been reported. The EMD of the $\text{Pr}_2\text{Fe}_{17}$ is not changed upon nitrogenation. Therefore, it is interesting to study whether the FOMP is still present in $\text{Pr}_2\text{Fe}_{17}\text{N}_x$. The magnetization at various temperatures from 4.2 to 300 K of magnetically aligned $\text{Pr}_2\text{Fe}_{17}\text{N}_x$ was measured with the field applied in the [001] direction. In Fig. 2, the measurements at 4.2 and 300 K are shown. No indication of an anomaly is found in the magnetization curve in the [001] direction, suggesting that the FOMP found in $\text{Pr}_2\text{Fe}_{17}$ is suppressed after nitrogenation. The absence of any anomaly in the magnetization curve of $\text{Pr}_2\text{Fe}_{17}\text{N}_x$ has also been reported by Isnard *et al.*¹⁰ The FOMP is a field-induced magnetic phase transition¹¹ which is strongly related to the magnetic anisotropy. In $\text{R}_2\text{Fe}_{17}\text{N}_x$ compounds containing a magnetic R ion, both the R- and the Fe-sublattice contribute to the total magnetic anisotropy. The Fe-sublattice anisotropy does not show any anomaly in the temperature dependence. It can therefore be concluded that, in general, the crystalline electric field acting on the magnetic R^{3+} ions cause the FOMP transitions. Figure 3 shows the magnetization curves measured on magnetically aligned $\text{Nd}_2\text{Fe}_{17}\text{N}_{2.95}$. Similar to what was found in $\text{Pr}_2\text{Fe}_{17}\text{N}_{2.7}$, no FOMP transition is detected for $\text{Nd}_2\text{Fe}_{17}\text{N}_{2.95}$ in [001] direction where a FOMP exists in the corresponding $\text{Nd}_2\text{Fe}_{17}$. The same is true for $\text{Tb}_2\text{Fe}_{17}\text{N}_2$.

As discussed above, $\text{Sm}_2\text{Fe}_{17}$ is the only compound of the whole R_2Fe_{17} series having the EMD changed from basal plane in $\text{Sm}_2\text{Fe}_{17}$ to c axis in $\text{Sm}_2\text{Fe}_{17}\text{N}_x$. The magnetic alignment of fine particles of $\text{Sm}_2\text{Fe}_{17}\text{N}_{7.9}$ was made by us-

ing the conventional static-field-alignment method. In Fig. 4, the magnetization measured on magnetically aligned $\text{Sm}_2\text{Fe}_{17}\text{N}_{2.9}$ is shown. It is evident that the magnetic anisotropy of $\text{Sm}_2\text{Fe}_{17}\text{N}_{2.9}$ is huge. At 300 K, a field strength of 23 T in hard direction is not yet enough to get the magnetization saturated. Liu *et al.*¹² reported that, at 4.2 K, the magnetization in the hard direction is not saturated at a field strength of 38 T.

Swift high energy (5 GeV) Pb ion irradiation has been employed to create defects in the high performance permanent magnet material $\text{Sm}_2\text{Fe}_{17}\text{N}_3$. Total ion fluences in the range from 10^{11} to 2×10^{13} ions/cm² were studied. In Mössbauer spectra at 26 and 300 K, both a paramagnetic doublet and a broad ferromagnetic contribution characteristic of an amorphous or strongly disordered phase are found to be induced by irradiation. Magnetization reversal was studied and coercivity is found to increase upon irradiation, up to fivefold at 5 K ($\mu_0 H_c = 1.5$ T) for the highest ion fluence. Initial magnetization curves of the irradiated samples are characteristic of material with a pinning type coercivity mechanism with a maximum initial depinning field of 0.4 T for the highest fluence. Magnetization measurements made parallel and perpendicular to the ion beam direction suggest that the defects created are highly anisotropic in shape. The temperature dependence of the coercivity has been analyzed within the framework of the Gaunt model of domain wall pinning. © 1998 American Institute of Physics. [S0021-8979(98)19811-0]

I. INTRODUCTION

Magnetization reversal in hard magnetic materials with magnetocrystalline anisotropy is generally described within the framework of a nucleation/propagation model. Magnetization reversal is a three step process: first nucleation of a small volume of reverse magnetization at defects such as inclusions, precipitates, or grain boundaries with the formation of a domain wall at the defect-matrix boundary; then transfer of this domain wall to within the hard matrix phase and finally its propagation through the whole grain in order to achieve full reversal. Depending on which of these stages dominates, one talks of nucleation or pinning-type coercivity. As most permanent magnets are of the nucleation type, a considerable amount of experimental and numerical work has been devoted to magnetization processes in such systems.¹ Given the complexity of the microstructure in real magnets, recent attempts have focused on model systems formed either by diluting the matrix phase in a nonmagnetic phase or by patterning thin films into arrays of identical, noninteracting particles.^{2,3} So far much less attention has been devoted to pinning-type systems. One-dimensional calculations predict the pinning force to be maximum when the defect size is comparable to the domain wall width δ_w .⁴ As high performance metallic permanent magnets are generally intermetallic $3d-4f$ compounds, the magnetocrystalline anisotropy is very large, thus leading to domain wall widths of a few nanometers.⁵ An increase in coercivity may therefore

be expected for nanometer-scale defects. Swift heavy ions are known to create nanometer sized defects in some metallic targets.⁶ Latent tracks have been observed in metals when the energy deposited by electronic excitations is above a threshold value.⁷ The configuration of the latent tracks gradually changes from strings of small separated damaged droplets to more or less homogeneously damaged cylinders as the electronic stopping power is increased above this threshold.

Pinning has already been observed in ion-irradiated garnets, where the domain walls are wide, after appropriate chemical etching of the damage tracks.⁸ In this article, we report on the direct development of pinning type coercivity by the controlled creation of defects by swift heavy ion irradiation. The material studied is $\text{Sm}_2\text{Fe}_{17}\text{N}_3$ ($\delta_w = 3.4$ nm), an intermetallic $3d-4f$ compound which exhibits much potential as a permanent magnet material, e.g., large magnetization, large uniaxial anisotropy, and high Curie temperature.⁹

II. EXPERIMENTAL DETAILS

$\text{Sm}_2\text{Fe}_{17}$ powder with a particle size of 20–65 μm was nitrided in a flowing mixed gas ($\text{NH}_3 + \text{H}_2$) system. Traces of a Sm rich phase were found in the parent material. To prepare samples for ion irradiation, the powder was mixed with epoxy resin (2:1 by wt) and sandwiched between two 15 μm sheets of Al foil. The thickness of the powder and epoxy mixture was then reduced to 50 μm by lamination in a roller mill. Several square sections (16 mm²) were then cut from the same sheet and irradiated with a 5 GeV Pb^{56+} ion beam at the GANIL accelerator in Caen, France. The total fluence

^{a)}Electronic mail: ndempsey@vax1.tcd.ie

FIG. 1. Mössbauer spectra of a nonirradiated reference sample ($\Phi = 0$ ions/cm²) and the sample irradiated with highest fluence ($\Phi = 2 \times 10^{13}$ ions/cm²) at room temperature.

ranged from 10^{11} to 2×10^{13} ions/cm². The penetration depth of the ions in the magnetic material was estimated from the TRIM code¹⁰ to be of the order of 100 μm . Mössbauer spectroscopy was carried out at 26 K and at room temperature with a ⁵⁷Co source in a rhodium matrix. Magnetic measurements were performed between 5 K and room temperature on an 8 T vibrating sample magnetometer (VSM) and a 10 T extraction magnetometer.

III. RESULTS AND DISCUSSION

Mössbauer analysis was used to evaluate the total amount and magnetic nature of the defect induced by irradiation. The room temperature Mössbauer spectra of a reference sample and of the sample irradiated at the highest fluence are given (Fig. 1). In the reference sample, about 3% of a paramagnetic phase is detected. This may be attributed to the decomposition products of the Sm rich trace phase during the $\text{NH}_3 + \text{H}_2$ heat treatments.¹¹ The spectrum of the irradiated sample has an additional paramagnetic doublet centered about zero velocity and a broad ferromagnetic contribution characteristic of an amorphous or strongly disordered phase. The total paramagnetic contribution accounts for about 17% of the Fe atoms. The quantity of the additional broad ferromagnetic contribution is estimated to be about 35%. The ratio of the additional paramagnetic to ferromagnetic phases decreases from 1:2 at room temperature to 1:3.5 at 26 K. These results indicate that the defects created are not of a uniform magnetic nature. This is not surprising as it is known that in Fe-based intermetallic alloys the magnetic configuration is very dependent on the Fe-Fe interatomic distances as well as on their coordination number. A core and shell defect of a different magnetic structure may thus be envisaged.

The fraction of the total surface damaged, p , may be expressed as a function of the total fluence, Φ , and the area of a latent track of radius r ,

$$p(\Phi, r) = 1 - \exp(-\pi r^2 \Phi). \quad (1)$$

Assuming a minimum defect radius of about 1.5 nm, based on the results from other metals (Ref. 7), we expect about

FIG. 2. Hysteresis loops of a reference sample (nonirradiated) together with those of the samples irradiated at 10^{12} (solid square), 5×10^{12} (solid circles), and 2×10^{13} ions/cm², measured at 5 K.

75% of the sample to be damaged at a fluence of 2×10^{13} ions/cm² if the defects are continuous tracks. As Mössbauer measurements indicate a maximum of 52% damage, at this fluence discontinuous tracks are most likely.

The hysteresis loops of some irradiated samples, measured at 5 K, are compared with that of a reference nonirradiated sample (Fig. 2). The coercive field is defined as the field at which the irreversible susceptibility is maximum. It increases upon irradiation, up to fivefold for the highest fluence of 2×10^{13} ions/cm², where we have made the approximation that $(\chi_{\text{irr}}) \approx (dM/dH)$. The initial magnetization curves of the reference sample and the two samples of highest fluence are given (Fig. 3). In the reference sample, the initial susceptibility is large which indicates free motion of the domain walls, as expected for large multidomain particles. In the irradiated samples, the initial susceptibility is practically zero until a critical field is reached. Such a behavior is generally ascribed either to single domain particles or to domain wall pinning in multidomain particles. As the size of the ferromagnetic particles is many times the critical single-domain particle size ($d_c = 0.3 \mu\text{m}$), the former is irrelevant. This critical field, H_p , thus corresponds to the minimum field required to depin the domain walls from the irradiation induced defects. The coercive and depinning

FIG. 3. Virgin magnetization curve of a reference sample (nonirradiated) together with those of the samples irradiated with 5×10^{12} and 2×10^{13} ions/cm², measured at 5 K.

FIG. 4. Coercive and initial depinning fields as a function of ion fluence measured at 5 K.

fields measured at 5 K are plotted as a function of the ion fluence (Fig. 4).

Magnetization measurements made in-plane and out-of-plane, i.e., perpendicular and parallel to the direction of the ion beam, are reported for a total ion fluence of 1×10^{13} ions/cm² (Fig. 5). The out-of-plane coercivity is significantly higher than the in-plane coercivity. However, no difference is observed in a reference sample. The pinning of a domain wall by spherical defects within a ferromagnetic grain should be independent of the orientation of the domain wall. This is not the case for cylindrical defects, a wall which is parallel to and travelling towards the defect should be pinned when it meets the defects as it is then in a minimum energy position [Fig. 5 inset (a)]. However, a wall which lies perpendicular to the defect and is travelling along its axis will not be pinned, as it will always be at the same energy [Fig. 5 inset (b)]. In an isotropic sample, the domain walls, which align with the easy axis of the grain, are randomly oriented. Grains which have their easy axis parallel to the applied field contribute most to the $M(H)$ curve near H_c as it

FIG. 5. Demagnetization curves of an ion irradiated sample (10^{13} ions/cm²) measured out-of-plane [(OOP), full circle] and in-plane [(IP), empty circles]. The derivatives of the fitted magnetization data which indicate values of coercivity of 1.8 and 1.3 T for the OOP and IP measurements, respectively, are also given. Schematic diagrams of a domain wall travelling (a) parallel and towards and (b) perpendicular and along a cylindrical defect are included.

is the projection of M along H which is measured. Therefore, a difference in the value of coercivity measured out-of-plane and in-plane for an isotropic sample reflects a difference in the coercivity of grains with domain walls travelling parallel and towards the ion path compared with grains where the domain walls are travelling perpendicular and along the ion path. These results support the evidence for extended defects, though we can conclude the tracks are discontinuous or continuous.

Gaunt has studied the pinning of domain walls in ferromagnetic materials.¹² If the unpinning process involves breakaway from a single defect, and the volume swept out by the wall contains, on average, one replacement pin then we are dealing with "strong pinning." "Weak pinning" involves the cooperative breakaway from many pinning sites and pinning is due to a fluctuation in the pinning site density. The predicted temperature dependence of coercivity is different for each regime. The temperature dependence of the coercivity of the sample irradiated with highest fluence has been analyzed and the observed result may be accounted for by weak pinning.¹³

IV. CONCLUSION

It has been established that significant increases in coercivity may be induced in coarse grained multidomain $\text{Sm}_2\text{Fe}_{17}\text{N}_3$ by irradiation with swift high energy heavy ions. Initial magnetization curves of the irradiated samples are characteristic of material with a pinning type coercivity mechanism. Mössbauer analysis reveals that the irradiation induced defects have both paramagnetic and ferromagnetic contributions, a core-shell structured defect is suggested. Quantitative analysis of the spectra as well as magnetization measurements indicate that the defects are highly anisotropic in shape and discontinuous. The temperature dependence of the coercivity may be explained within the framework of the Gaunt model of weak pinning.

In order to apply the hydrogenation-disproportionation-desorption-recombination process for the preparation of highly coercive $\text{Sm}_2\text{Fe}_{15}\text{Ga}_2\text{C}_y$, which exhibits excellent magnetic properties together with a high thermal stability, the disproportionation of $\text{Sm}_2\text{Fe}_{17-x}\text{Ga}_x$ was investigated. A systematic study of the hydrogen absorption behavior of $\text{Sm}_2\text{Fe}_{17-x}\text{Ga}_x$ ($x=0, 0.5, 1$, and 2) at hydrogen pressures between 0.5 and 8 bar by means of hydrogen differential thermal analysis (HDTA) showed that increased hydrogen pressures promote the disproportionation of the stabilized $2:17$ phase. X-ray diffraction investigations of the HDTA samples showed a decreasing content of the $2:17$ phase for increasing hydrogen pressures. It was possible to achieve a nearly full disproportionation even for the most stable compound $\text{Sm}_2\text{Fe}_{15}\text{Ga}_2$ by applying a pressure of 8 bar. Microstructural changes within the disproportionated mixture as a result of the applied pressure have been documented in detail by high resolution scanning electron microscopy. © 1998 American Institute of Physics. [S0021-8979(98)22611-9]

Highly stable and coercive $\text{Sm}_2\text{Fe}_{17-x}\text{Ga}_x\text{C}_y$ materials ($1 \leq x, y \leq 3$) produced by melt spinning¹ or mechanical alloying² are candidates for a new class of permanent magnets. The hydrogenation-disproportionation-desorption-recombination (HDDR) process is another, very effective method for the production of highly coercive $\text{Sm}_2\text{Fe}_{17}\text{N}_y/\text{C}_y$ powders.³⁻⁵ In this process, coarse grained $\text{Sm}_2\text{Fe}_{17}$ disproportionates into an intimate mixture of SmH_z ($1.9 \leq z \leq 2.8$) and $\alpha\text{-Fe}$. In the second step, the hydrogen is desorbed and the constituents recombine into a fine grained microstructure. This material exhibits a high coercivity after subsequent nitrogeneration or carburization.⁶ However, the partial substitution of Fe by Ga in $\text{Sm}_2\text{Fe}_{17}$ stabilizes the $2:17$ phase against disproportionation by hydrogen. Therefore it is impossible to complete the HDDR process for a Ga content $x > 0.5$ under standard conditions.⁷ In this work the hydrogenation and disproportionation step was carried out under increased hydrogen pressure, using pressures up to 8 bar in order to achieve complete disproportionation of $\text{Sm}_2\text{Fe}_{17-x}\text{Ga}_x$ with $x=1$ and 2 into SmH_z and $\alpha\text{-(Fe,Ga)}$.

Elemental Sm, Fe, and Ga (purities 99.9%) were arc melted to form prealloys. The prealloys were melted together with additional Fe in an induction furnace. A Sm excess of 30% was used to compensate for evaporation losses and to reach nominal compositions of $\text{Sm}_2\text{Fe}_{17-x}\text{Ga}_x$ with $x=0, 0.5, 1$, and 2 . The samples were homogenized in an inert gas atmosphere at 1050°C for 72 h. The resulting material was crushed into particles with diameters below $100\text{ }\mu\text{m}$.

The hydrogen absorption behavior was investigated by hydrogen differential thermal analysis (HDTA). For each experiment about 180 mg samples were heated in hydrogen at pressures between 0.5 and 8 bar with a heating rate of 5

K/min. After heating up to 950°C the samples were cooled down in hydrogen atmosphere. Phase changes during disproportionation were observed by x-ray diffraction (XRD) using $\text{Cu K}\alpha$ radiation. Microstructural changes were investigated by means of high resolution scanning electron microscopy (HRSEM Hitachi S-4000 FE) in the backscattered mode.

HDTA experiments at hydrogen pressures of $0.5, 1, 2, 4$, and 8 bar were carried out for all samples. The HDTA curves in Fig. 1 show the temperature difference ΔT between sample pan and reference pan for $\text{Sm}_2\text{Fe}_{16}\text{Ga}$ during heating in hydrogen atmosphere. The ΔT peaks between 550 and 800°C are related to an exothermic reaction which can be attributed to the disproportionation of $\text{Sm}_2\text{Fe}_{16}\text{Ga}$. For increasing hydrogen pressures the temperature, at which the

FIG. 1. HDTA curves of $\text{Sm}_2\text{Fe}_{16}\text{Ga}$ for different hydrogen pressures. The exothermic peaks are related to the disproportionation of $\text{Sm}_2\text{Fe}_{16}\text{Ga}$ into SmH_z and $\alpha\text{-(Fe,Ga)}$ and it can be seen that an increased hydrogen pressure promotes the disproportionation reaction.

FIG. 2. Disproportionation temperatures of $\text{Sm}_2\text{Fe}_{17-x}\text{Ga}_x$ ($x=0, 0.5, 1$, and 2) for different pressures; plotted in the form T against $\log p$, reasonably linear relationships are obtained.

disproportionation peak occurs, decreases. This decrease can be explained in terms of a decrease of the free enthalpy of samarium hydride with increasing hydrogen pressure, which promotes the disproportionation reaction and increases the kinetics of this reaction. The effect of hydrogen pressure in this case is very similar to that found for the disproportionation of $\text{Nd}_2\text{Fe}_{14}\text{B}$.⁸ The same behavior was observed for all $\text{Sm}_2\text{Fe}_{17-x}\text{Ga}_x$ samples with $x=0, 0.5, 1$, and 2 . The temperatures, at which the disproportionation peaks occur, are given in Fig. 2 for all samples and pressures. For $\text{Sm}_2\text{Fe}_{15}\text{Ga}_2$, it was only possible to detect one peak, connected to the disproportionation at the highest pressure. For hydrogen pressures below 8 bar, the disproportionation reaction of this material was too sluggish to result in a defined exothermic peak. With increasing Ga content, the disproportionation occurs at increasing temperatures due to the enhanced stability of the 2:17 structure against the disproportionation by hydrogen. A similar effect was observed for the disproportionation of Ga-containing $\text{Nd}_2\text{Fe}_{14}\text{B}$ alloys.⁹ The fact that the Ga addition to the $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase increases the stability against disproportionation was reported earlier.^{10,11} Thermodynamic model calculations showed that an increased stability of the $\text{Nd}_2(\text{Fe}, \text{Ga})_{14}\text{B}$ phase is caused by the substitution of Fe by Ga because of a less negative hydride formation enthalpy compared to that of the ternary $\text{Nd}_2\text{Fe}_{14}\text{B}$ compound.¹² The partial substitution of Fe by Ga in $\text{Sm}_2\text{Fe}_{17}$ seems to have a similar effect.

The HDTA samples were also investigated by XRD and HRSEM. The XRD patterns of the HDTA treated $\text{Sm}_2\text{Fe}_{16}\text{Ga}$ samples corresponding to Fig. 1 are presented in

FIG. 3. XRD patterns of $\text{Sm}_2\text{Fe}_{16}\text{Ga}$ after hydrogen treatment at different pressures (corresponding to Fig. 1). Main reflections originate from α -(Fe,Ga) and SmH_2 ; remaining reflections of the nondisproportionated 2:17 phase disappear with increasing hydrogen pressures.

Fig. 3. Although there was only a very weak exothermic peak of the disproportionation at a pressure of 0.5 bar (see Fig. 1), the XRD patterns are dominated by the α -(Fe,Ga) and SmH_2 reflections, even for this relatively low pressure. The HRSEM images in Figs. 4(a) and 4(b) show the partially disproportionated structure of the $\text{Sm}_2\text{Fe}_{16}\text{Ga}$ sample after HDTA at 0.5 bar. Figure 4(a) shows a detail of the reaction front between the gray region of nondisproportionated 2:17 phase in the upper left corner and the disproportionated mixture of SmH_2 (bright) and α -(Fe,Ga) (dark). In the vicinity of the nondisproportionated phase, the disproportionated mixture has a lamellae-like appearance. Okada *et al.*¹³ characterized the microstructural changes during the HDDR reactions of $\text{Sm}_2\text{Fe}_{17}$ by transmission electron microscopy. They observed a similar disproportionated microstructure which was described as rodlike or spherical SmH_2 particles embedded in an α -Fe matrix. A similar microstructure consisting of NdH_2 rods in an α -Fe matrix has been observed in disproportionated NdFeB -type material.¹⁴ According to these references, we suggest that the lamellae-like structures in Fig. 4(a) are in fact SmH_2 rods embedded in α -Fe. The very fine SmH_2 rods with diameters of about 20 nm are formed during the eutectoid-type disproportionation reaction. This initial stage of the disproportionation reaction is very well observable due to the extremely slow reaction speed under the applied conditions. With increasing distance from the reaction front, i.e., with increasing disproportionation time, the SmH_2 rods increase in diameter to about 150 nm and their shape transforms into a more irregular three-dimensional one. Similar coarsening processes had been observed for disproportionated $\text{Sm}_2\text{Fe}_{17}$ and NdFeB -type alloys.^{13,15} Figure 4(b) shows an image with lower magnification in order to give an overview of the partially disproportionated structure in the sample. The intensities of the reflections of the nondisproportionated 2:17 phase in the XRD patterns in Fig. 3 decrease with increasing pressure and the reflections disappear completely after the HDTA treatment at 8 bar. The fully

FIG. 4. HRSEM images of $\text{Sm}_2\text{Fe}_{16}\text{Ga}$ after HDTA. Figure 4(a) shows a detail of the reaction front between nondisproportionated 2:17 phase (gray, upper left corner) and the disproportionated mixture of SmH_2 (white) and $\alpha\text{-Fe}$ (black). A coarsening of the SmH_2 phase with increasing distance from the reaction front is observable. Figures 4(b) and 4(c) show the different degrees of disproportionation of $\text{Sm}_2\text{Fe}_{16}\text{Ga}$ after HDTA at 0.5 and 8 bar, respectively.

disproportionated $\text{Sm}_2\text{Fe}_{16}\text{Ga}$ material is shown in the HRSEM image in Fig. 4(c). The fine grained mixture of SmH_2 and $\alpha\text{-(Fe,Ga)}$ extends over the entire sample and remains of nondisproportionated 2:17 phase cannot be found. Again, very fine and somewhat coarser regions can be observed within the disproportionated mixture.

The results of the XRD investigation of $\text{Sm}_2\text{Fe}_{15}\text{Ga}_2$ after HDTA at different pressures are in good agreement with the results obtained for $\text{Sm}_2\text{Fe}_{16}\text{Ga}$. The intensity of the remaining 2:17 reflections of $\text{Sm}_2\text{Fe}_{15}\text{Ga}_2$ (not shown) is larger due to the higher stability of the Ga richer compound against the disproportionation. However, the reflections associated with the 2:17 structure have almost disappeared after the HDTA treatment at 8 bar.

In order to develop a submicron-grained hard magnet via the HDDR route, the disproportionated alloy has to recombine into the original 2:17-type phase. However, one possibility is that the alloy recombines into the disordered TbCu_7 -type structure.⁴ An investigation of HDDR processes in $\text{Sm}_2\text{Fe}_{17-x}\text{Ga}_x$ by means of reactive grinding showed that the Ga substitution stabilizes the 1:7 structure.¹⁶ Desorption and recombination experiments on alloys studied in the present work, which were disproportionated by means of high hydrogen pressures, are still in progress.

In summary, an enhanced hydrogen pressure has a favorable effect on the disproportionation of $\text{Sm}_2\text{Fe}_{17-x}\text{Ga}_x$. The complete disproportionation of the samples with high Ga content under increased hydrogen pressures is very promising for an application of the HDDR process for the preparation of highly stable and coercive gas carbonated $\text{Sm}_2\text{Fe}_{17-x}\text{Ga}_x\text{C}_y$ powders, which could be used for the production of fully dense permanent magnets by hot compaction.

Electron microscopy studies of high coercive melt-spun $\text{Sm}_{2+\delta}\text{Fe}_{15}\text{Ga}_2\text{C}_2$ permanent magnets

J. van Lier,^{a)} A. Zern, H. Labitzke, J. Thomas, M. Seeger, and H. Kronmüller
Max-Planck-Institut für Metallforschung, Heisenbergstr. 1, D-70569 Stuttgart, Germany

The influence of over-stoichiometric Sm contents on the magnetic properties of melt-spun Ga stabilized $\text{Sm}_2\text{Fe}_{17}$ carbides has been investigated. For optimum heat treated $\text{Sm}_{2+\delta}\text{Fe}_{15}\text{Ga}_2\text{C}_2$ ribbon flakes an increase of the room temperature coercivity could be observed from $\mu_0 H_C = 1.5$ T for stoichiometric samples to $\mu_0 H_C = 2.2$ T for $\delta = 0.15$. This effect is very interesting because of the improved temperature stability. At 500 K a maximum energy density of $(BH)_{\text{max}} = 31.4$ kJ/m³ for $\delta = 0.09$ can be observed. It is assumed that a Sm-rich nonmagnetic intergranular phase decouples the grains magnetically and is consequently the origin of the high coercivities of these samples. Electron microscopy studies of these melt-spun $\text{Sm}_{2+\delta}\text{Fe}_{15}\text{Ga}_2\text{C}_2$ samples with different Sm contents have been performed by scanning electron microscopy (SEM) and transmission electron microscopy (TEM). A broad grain size distribution (50–250 nm) is observed in the SEM, but there is no difference among samples with different Sm contents. TEM studies show no change in grain shape with variation of the δ value. High resolution TEM (HRTEM) studies indicate the existence of a very thin intergranular phase for samples with an excess of Sm which was proved using high resolution energy dispersive x-ray analysis (EDX) studies with a scanning TEM. These investigations show a significant increase of the Sm content at the grain boundaries for these highly coercive samples. © 1998 American Institute of Physics. [S0021-8979(98)16011-5]

I. INTRODUCTION

The magnetic properties of the binary alloy $\text{Sm}_2\text{Fe}_{17}$ can be changed drastically by interstitial modifications of the rhombohedral $\text{Th}_2\text{Zn}_{17}$ structure. The planar anisotropy can be altered by carburation or nitrogenation to a uniaxial one with high anisotropy fields and a simultaneous increase of the Curie temperature by more than 250 K.¹ For example, for $\text{Sm}_2\text{Fe}_{17}\text{C}_2$ values of $\mu_0 H_A \approx 16$ T and $T_C \approx 670$ K are observed.² Full-potential linear-muffin-tin-orbital calculations have shown that the volume expansion favorably influences the magnetic properties of the hexagonal and rhombohedral $\text{RE}_2\text{Fe}_{17}$ alloys whereas the chemical effect of the interstitial atoms detracts from them.^{3,4} But these $\text{Sm}_2\text{Fe}_{17}(\text{N,C})_y$ alloys decompose at $T = 600\text{--}700$ °C into $\text{Sm}(\text{N,C})$ and $\alpha\text{-Fe}$. In the case of carbides, the decomposition can be suppressed to temperatures up to $T \approx 1000$ °C by substituting Ga for Fe.⁵

II. SAMPLE PREPARATION

We have prepared several $\text{Sm}_{2+\delta}\text{Fe}_{15}\text{Ga}_2\text{C}_y$ samples with different Sm contents by remelting a Fe_{15}C_3 prealloy in an arc furnace together with elementary Sm and Ga for several different times under argon atmosphere. The purity of the elements was at least 99.9%. The best magnetic properties could be reached for all compositions by melt spinning the ingots into mainly amorphous ribbons followed by a subsequent crystallization treatment at 775 °C for 15 min under high vacuum. Both Sm and C evaporate during this proce-

dures. Chemical analyses determined Sm contents of $-0.05 \leq \delta \leq 0.19$ and a carbon content of $y = 2.18 \pm 0.05$ for all samples.

For the microstructural observations in the scanning electron microscope (SEM) the ribbon flakes were broken so that the cross sections of the ribbon flakes could be investigated. The plan-view transmission electron microscope (TEM) samples were prepared by electrochemical polishing followed by Ar-ion-beam milling. To suppress changes of the microstructure during ion milling the samples were cooled with liquid N₂.

III. RESULTS AND DISCUSSION

The magnetic measurements were performed in a PAR vibrating sample magnetometer (VSM). The $\text{Sm}_{2+\delta}\text{Fe}_{15}\text{Ga}_2\text{C}_2$ samples exhibit a well squared hysteresis loop and only a small field range in which the demagnetization takes place.⁶ The coercivity of the samples is nearly independent of Sm content with values of $\mu_0 H_C \approx 1.5$ T ($T = 300$ K) for $\delta \leq 0.03$ as shown in Fig. 1. These values are in good agreement with recent results for stoichiometric mechanical alloyed, intense ball milled and melt-spun $\text{Sm}_2\text{Fe}_{17-x}\text{Ga}_x\text{C}_y$ samples.⁷⁻⁹ But for higher Sm contents the coercivity is drastically enhanced with a saturation-like behavior at $\mu_0 H_C \approx 2.2$ T for $\delta \geq 0.09$. The demagnetization curve of the sample with $\delta = 0.19$ exhibits two steps with two different critical fields ($\mu_0 H_{\text{crit}}^1 \approx 0.7$ T, $\mu_0 H_{\text{crit}}^2 \approx 2.2$ T) leading to a lower coercivity. We assume that this is affected by a small amount of a second hard magnetic phase occurring for high Sm contents. The vertical dotted line in Fig. 1 indicates the end of the stability range of the 2:17 phase.

As the maximum energy density $(BH)_{\text{max}}$ at elevated temperatures is governed by irreversible demagnetization

^{a)}Electronic mail: vanlier@vaxph.mpi-stuttgart.mpg.de

FIG. 1. Coercive field $\mu_0 H_c$ vs Sm excess δ at room temperature for samples of the $\text{Sm}_{2+\delta}\text{Fe}_{15}\text{Ga}_2\text{C}_2$. The vertical dotted line indicates the end of the stability range of the left phase.

processes, the enhanced coercivities improve the temperature stability of the magnets. At $T=500$ K the maximum energy density is enlarged from $(BH)_{\text{max}}^{500\text{ K}} = 25 \text{ kJ/m}^3$ for stoichiometric compounds to $(BH)_{\text{max}}^{500\text{ K}} = 31.4 \text{ kJ/m}^3$ for $\delta=0.09$.

The drastic effect of δ on the extrinsic property $\mu_0 H_c$ which was found in the whole ferromagnetic temperature range could not be correlated to a change of intrinsic magnetic properties. The intrinsic properties especially the anisotropy constants K_1 and K_2 , which were determined in the temperature range from $T=80$ K to $T=570$ K for three samples with different Sm contents ($\delta = 0.03, 0.05, 0.09$),⁶ are independent of the Sm content. Also, the Curie temperature T_C is not affected by δ . A detailed analysis of temperature dependent hysteresis measurements within the nucleation model^{10,11} shows that over-stoichiometric Sm in $\text{Sm}_{2+\delta}\text{Fe}_{15}\text{Ga}_2\text{C}_2$ magnets reduces the effect of internal

FIG. 2. SEM micrographs of $\text{Sm}_{2+\delta}\text{Fe}_{15}\text{Ga}_2\text{C}_2$ samples with $\delta=-0.05$ (a) and $\delta=0.19$ (b).

FIG. 3. TEM micrographs of $\text{Sm}_{2+\delta}\text{Fe}_{15}\text{Ga}_2\text{C}_2$ samples with $\delta=0.00$ (a) and $\delta=0.11$ (b).

stray fields on the coercivity.¹² Combining this information leads to the assumption that the change of the coercivity is forced by a Sm-rich nonmagnetic intergranular phase which decouples the grains magnetically comparable to Nd-rich $\text{Nd}_2\text{Fe}_{14}\text{B}$ permanent magnets.^{13,14} To prove this and to exclude the influence of other changes in the microstructure we performed different electron microscopy studies.

A high resolution field emission SEM DSM 982 GEMINI (Zeiss) was used to investigate the grain size of the annealed ribbon flakes. Figures 2(a) and 2(b) shows the micrographs of the cross sections for two samples with $\delta=-0.05$ and $\delta=0.19$, respectively. A broad grain size distribution can be observed for both samples, with comparable fractions of coarse and fine grains. At a higher magnification the grain sizes can be estimated to be $d \approx 50$ nm in the finely grained regions at the wheel side of the ribbon and $d \approx 250$ nm in the coarsely grained regions on the gas side. But there is no difference for samples with different Sm contents.

Conventional TEM and high resolution TEM (HRTEM) studies were performed in a JEOL JEM 4000 FX electron microscope at an acceleration voltage of 400 kV. No significant differences between samples with different Sm contents could be observed considering the shape of the grains as shown in the TEM micrographs of Fig. 3 in the case of $\delta=0.00$ [Fig. 3(a)] and $\delta=0.11$ [Fig. 3(b)]. The grains of both samples are very irregular and have very sharp edges and bent surfaces, leading to large stray fields and consequently to relatively low coercivities compared to the theo-

FIG. 4. HRTEM micrograph of a $\text{Sm}_{2+\delta}\text{Fe}_{15}\text{Ga}_2\text{C}_2$ sample with $\delta=0.11$.

retical upper limit $H_N^{\min} \approx 5.3$ T for isotropic magnets. The minimum nucleation field for misoriented grains H_N^{\min} is deduced from the nucleation model.

HRTEM investigations indicate the existence of a very thin intergranular phase for over-stoichiometric samples. This is shown in Fig. 4 for $\delta=0.11$ where this phase has a width of $b \approx 0.7$ nm. It should be mentioned that the average value of b is smaller and that this phase is often not visible because of canted orientations of the grain boundaries. This boundary phase was not found in stoichiometric samples.

To prove the existence of this intergranular phase we performed high resolution energy dispersive x-ray (EDX) analyses with a so called "dedicated scanning TEM (STEM)." The electron source of this STEM, dedicated for high resolution chemical analyses, is a cold field emission source with a beam diameter of 1 nm at a beam current of 1 nA and an energy bandwidth of less than 0.5 eV. The acceleration voltage was 100 kV and the EDX analyses were performed on a reduced area of $3 \text{ nm} \times 4 \text{ nm}$. The EDX spectra measured with a Noran HP Ge detector (high purity germanium) can only be analyzed qualitatively. We investigated several regions of the samples by a relative comparison of the compositions in the grain boundary phase and within the grains. The sample with $\delta=0.11$ exhibits an enhanced value of the Sm content in the grain boundaries. The difference of the average values measured for the Sm content in the grain

boundaries (13.1 at. %) and in the grains (12.2 at. %) is $\Delta\text{Sm} = 0.9$ at. %. As the width of the intergranular phase is only $b \approx 0.5$ nm, this phase has a contribution of only approximately 15% to the EDX measurement over the investigated area of $3 \text{ nm} \times 4 \text{ nm}$. This leads to a corrected change of the Sm content of $\Delta\text{Sm} \approx 5$ at. % which corresponds to a significant enhancement of the Sm content in the boundary phase of about 40%. In contrast to this, we found no differences in the compositions of grains and grain boundaries in the sample with $\delta=0.00$.

IV. CONCLUSION

We have reported a strong influence of the Sm content on the coercive field of melt-spun $\text{Sm}_{2+\delta}\text{Fe}_{15}\text{Ga}_2\text{C}_2$ permanent magnets which is not forced due to changes of the intrinsic properties. Furthermore, it was shown that neither the grain size nor the grain shape is affected by the Sm content. A Sm-enriched boundary phase could be observed in samples with over-stoichiometric Sm contents. This intergranular phase decouples the grains magnetically and is the reason for the enhanced coercivities and the improved magnetic properties at elevated temperatures.

Crystallographic properties of Nd₂Fe₁₇N₃ have been investigated using powder neutron diffraction techniques at pressures up to 7.3 GPa. With increasing pressure, the unit cell volume of Nd₂Fe₁₇N₃ decreases almost linearly at a rate of 6.1 Å³/GPa without undergoing a phase transformation or expelling the interstitial nitrogen atoms. The observed rate of contraction corresponds to a bulk modulus of 1.4×10^{11} N/m² for Nd₂Fe₁₇N₃. The unit cell volume of Nd₂Fe₁₇N₃ at 7.3 GPa is approximately equal to that of Nd₂Fe₁₇ at atmospheric pressure. Even though the unit cell of Nd₂Fe₁₇ expands anisotropically due to nitrogenation, contraction of the Nd₂Fe₁₇N₃ unit cell under pressure appears to be isotropic with lattice parameters *a* and *c* decreasing by approximately 1.8% as the sample pressure increases from ambient to 7.3 GPa. © 1998 American Institute of Physics. I. INTRODUCTION

The increase in Curie temperature which accompanies the interstitial nitrogenation¹ of R₂Fe₁₇ (R=rare earth) type intermetallics is generally attributed to the resulting longer near neighbor iron-iron distances. However, it has been pointed out^{2,3} that the relationships between near neighbor iron-iron distances and magnetic properties, especially the Curie temperature, of rare earth iron intermetallics are complex and not well understood.

Measuring the crystallographic and magnetic properties of a given sample under different pressures would enable one to study the direct correlation between the interatomic distances and magnetic interactions. High pressure magnetic properties, especially the Curie temperature, of several rare earth transition metal intermetallics have been reported by several workers,⁴⁻⁹ see Table I. Unfortunately, studies on structure-pressure relationships are less common and limited to measuring compressibility^{8,9} at different pressures and temperatures. However, more detailed information on structure-pressure relationships (dependence of the lattice parameters and interatomic distances on sample pressure) is necessary for a better understanding of the role played by interatomic distances in determining magnetic properties. Herein we report the preliminary results from a neutron diffraction study of Nd₂Fe₁₇N₃ at pressures up to 7.3 GPa.

II. EXPERIMENTAL METHODS

Nd₂Fe₁₇ samples were prepared from elements of purity 99.9% at. % or better by induction melting followed by annealing at 1000 °C for 72 h. Nd₂Fe₁₇N₃ was synthesized by

gas phase insertion of nitrogen into finely ground (maximum particle size was 50 μ) Nd₂Fe₁₇ at 450 °C and 10 MPa. The phase purity of the samples was checked by x-ray diffraction on a Guinier Hägg camera using Cu K_α radiation. The nitrogen content, lattice parameters, and atomic positions for the Nd₂Fe₁₇N₃ sample were determined from a powder neutron diffraction pattern obtained at 23 °C and atmospheric pressure at the University of Missouri Research Reactor (MURR) using 1.4766 Å neutrons. Neutron diffraction data obtained at MURR were refined using the FULLPROF code¹⁰ on the basis of the Th₂Zn₁₇-type structure.

Time of flight neutron diffraction patterns at high pressure were obtained at 23 °C on the high intensity powder diffractometer (HIPD) at the Manual Lujan, Jr. Neutron Scattering Center (MLNSCE), Los Alamos National Laboratory. The sample used was a wet mixture of approximately 90 mg of Nd₂Fe₁₇N₃ powder, 160 mg of NaCl powder, and Florinert

the high pressure experiment was obtained at atmospheric pressure on a Philips PW 1800/10 x-ray diffractometer using Cu K_α radiation. This x-ray diffraction pattern was analyzed using the FULLPROF code.¹⁰

III. RESULTS AND DISCUSSION

X-ray diffraction patterns of $\text{Nd}_2\text{Fe}_{17}\text{N}_3$ measured before the high pressure experiment, see Fig. 1(a), indicate that the sample is single phase except for a small amount of α -Fe. Analysis of the neutron diffraction pattern obtained at ambient pressure for $\text{Nd}_2\text{Fe}_{17}\text{N}_3$ at MURR confirmed the nitrogen content to be three per formula unit. All time-of-flight neutron diffraction data, see Fig. 2, could be fit based on the $\text{Nd}_2\text{Fe}_{17}\text{N}_3$ structure indicating that the sample did not undergo a phase transformation during exposure to high pressure.

Dependence of the lattice parameters and the unit cell volume of $\text{Nd}_2\text{Fe}_{17}\text{N}_3$ on sample pressure, see Table II, is shown in Figs. 3 and 4, respectively. The unit cell of $\text{Nd}_2\text{Fe}_{17}\text{N}_3$ contracts with increasing pressure at a rate of 6.1 Å³/GPa. This rate corresponds to a compressibility of 7×10^{-3} GPa⁻¹ or a bulk modulus of 14×10^{11} Nm⁻². The unit cell volume of $\text{Nd}_2\text{Fe}_{17}\text{N}_3$ at 7.3 GPa is approximately equal to that of $\text{Nd}_2\text{Fe}_{17}$ at atmospheric pressure. Even though the unit cell of $\text{Nd}_2\text{Fe}_{17}$ expands anisotropically when nitrogenated, contraction of the $\text{Nd}_2\text{Fe}_{17}\text{N}_3$ unit cell under pressure appears to be isotropic with both *a* and *c* lattice parameters decreasing by approximately 1.8% as the sample pressure increases from ambient to 7.3 GPa, see Table III.

The similarity of the lattice parameters and unit cell volume, obtained by refining the x-ray diffraction patterns shown in Fig. 1, of $\text{Nd}_2\text{Fe}_{17}\text{N}_3$ before and after the high pressure experiment, see Table III, strongly suggests that the interstitial nitrogen atoms were not expelled during exposure to high pressure even though the unit cell of $\text{Nd}_2\text{Fe}_{17}\text{N}_3$ was compressed down to the size of $\text{Nd}_2\text{Fe}_{17}$. The stability of $\text{Nd}_2\text{Fe}_{17}\text{N}_3$ under high pressure is in sharp contrast to its

TABLE III. The lattice parameters of $\text{Nd}_2\text{Fe}_{17}$ at ambient pressure, $\text{Nd}_2\text{Fe}_{17}\text{N}_3$ at ambient pressure before and after the high pressure experiment, and $\text{Nd}_2\text{Fe}_{17}\text{N}_3$ at 7.3 GPa.

thermal instability which leads to expulsion of nitrogen by decomposition when heated beyond 550 °C.¹⁵

Results discussed herein have established the need to measure the Curie temperature of $\text{Nd}_2\text{Fe}_{17}\text{N}_3$ at comparable pressures. Such an experiment is now in the design stage.

The title compounds were confirmed to have the Th_2Zn_{17} type rhombohedral structure (space group $R\bar{3}m$) except for $Ho_2Fe_{16}Al$ and $Ho_2Fe_{15}Al_2$ which have the Th_2Ni_{17} type hexagonal structure (space group $P6_3/mmc$) while $Ho_2Fe_{13}Al_3$ is a mixture of the two phases with the hexagonal phase dominant. A larger unit cell favors the formation of an ordered rhombohedral phase rather than a disordered hexagonal phase. Both the substitution of Fe by Al and the insertion of C can expand the cell and lead to the formation of an ordered rhombohedral phase. The site preferences of Al are somewhat different with and without C. In both series, C is mainly found at the $9e$ interstitial site.

I. INTRODUCTION

It is well known that both the insertion of C and N^{1-3} and the substitution of Fe by Al, Ga, Si^{4-8} can lead to a great enhancement in the magnetic properties of the rare-earth transition metal compounds. One advantage of the carbides over the nitrides is that C atoms cannot only be introduced into the compounds from gas phase reaction but can also be introduced directly from melting, leading to better thermodynamic stability. The upper limit for C concentration by gas phase insertion is near 3 C atoms per formula unit with a fully filled octahedral $9e$ site. However, it is hard to introduce more than one C atom/f.u. from the melt. It was found that with certain substituents for Fe, such as Ga and Al, higher C concentration (>2 C atoms/f.u.) can be achieved in some 2-17 carbides.⁹⁻¹¹ As part of a comprehensive study on the effect of combined substitutional-interstitial modification on the structure and magnetic properties of the rare-earth $(RE)_2Fe_{17}$ compounds, especially with a higher substituent concentration, $Tb_2Fe_{17-x}Al_xC$, $Ho_2Fe_{17-x}Al_x$, and $Ho_2Fe_{17-x}Al_xC$ ($x=1-4$) have been studied by neutron diffraction and magnetic measurements. The magnetic properties of the carbided samples were reported elsewhere.¹² Here we report the structural details of these samples.

II. EXPERIMENT

All samples were prepared by arc melting of the constituent elements of purity at least 99.9% in a high purity argon atmosphere at the National Chung Cheng University in Taiwan. For the carbided specimens, a master alloy of Fe_3C is first melted in a vacuum induction furnace from pure Fe metal and graphite. The samples were remelted several times and then homogenized at 1100 °C for 24 h. Neutron diffraction data were collected on less than 1g of powdered samples at the University of Missouri Research Reactor using the high resolution position-sensitive detector (PSD) diffractometer. The samples were contained in thin wall V cans

and were measured at room temperature. The neutron wavelength used was 1.7675 Å. The data were accumulated in 24 h with 2θ ranging from 5° to 105° in 0.05° steps. The neutron diffraction powder patterns were analyzed by the Rietveld method¹³ using the FULLPROF program for multi-phase refinement, including magnetic structure refinement. T_c was measured by thermogravimetric analysis (TGA).

III. RESULTS AND DISCUSSION

$Tb_2Fe_{17-x}Al_xC$, $Ho_2Fe_{17-x}Al_xC$, and $Ho_2Fe_{13}Al_4$ were confirmed to have the Th_2Zn_{17} type rhombohedral structure (space group $R\bar{3}m$) while $Ho_2Fe_{16}Al$ and $Ho_2Fe_{15}Al_2$ have the Th_2Ni_{17} type hexagonal structure (space group $P6_3/mmc$), and $Ho_2Fe_{14}Al_3$ is a mixture of the two phases with the hexagonal phase dominant (67 wt %). The refinement results for $Tb_2Fe_{17-x}Al_xC$ and $Tb_2Fe_{17-x}Al_x$ (data from Ref. 14) are shown in Table I and those for the Ho specimens are shown in Table II. All samples are almost free of α -Fe (<0.5 wt %).

From Tables I and II, it can be seen that the hexagonal Ho samples have the smallest unit cells. This indicates that the size of the unit cell is a determinant factor in forming either an ordered rhombohedral phase or a disordered hexagonal phase. The substitution of Fe with bigger Al atoms and/or the insertion of C atoms expand the cell and resemble the bonding for light (and larger) rare-earths which crystallize in the ordered rhombohedral structure. The unit cell volume increases about $2 \text{ Å}^3/\text{f.u.}/\text{Al atom}$, with or without C. A small deviation is found with $Ho_2Fe_{13}Al_4$, which may reflect the discontinuity from the phase transition. In the carbided samples, the effect of different C contents has been taken into consideration.

The Al site occupancies for $Tb_2Fe_{17-x}Al_xC$ and $Tb_2Fe_{17-x}Al_x$ are shown in Fig. 1. Compared with the data for $Tb_2Fe_{17-x}Al_x$, Al still prefers the Fe(18h) site and totally avoids Fe(9d) (not shown in the figure) in the carbided samples. The Al occupancies in the carbided samples at 18h are higher than that in samples without C. In $Tb_2Fe_{15}Al_2C$, Al has a lower occupancy at the Fe(6c) as compared to

$\text{Tb}_2\text{Fe}_{15}\text{Al}_2$, but the Al atoms fill up the 6c site more rapidly at a higher concentration which results in a higher 6c occupancy in $\text{Tb}_2\text{Fe}_{13}\text{Al}_4\text{C}$ than in $\text{Tb}_2\text{Fe}_{13}\text{Al}_4$. The behavior at the Fe(18f) site at higher concentration is just the opposite. C is found at the octahedral 9e site.

The behavior of the Al occupancies in $\text{Ho}_2\text{Fe}_{17-x}\text{Al}_x\text{C}$ (Fig. 2) is similar to that in the Tb carbides, namely Al atoms prefer the 18h site and fill up the 6c site more rapidly at higher concentration. C is only found at the 9e site. Because of the similarity in site environment between the hexagonal structure and the rhombohedral structure, the Al site occupancies shown in Table II for the hexagonal phase in

$\text{Ho}_2\text{Fe}_{17-x}\text{Al}_x$ ($x=1-3$) are those of equivalent sites in the rhombohedral structure. For the hexagonal structure, it is straightforward to figure out the Al occupancies at 6g, 12k, and 12j (equivalently 9d, 18h, and 18h in the rhombohedral structure, respectively) because there is no reason to believe these sites are not fully filled. The Al occupancies at the dumb bell 4e/4f sites can also be determined with the assumption that every possible dumb bell site is fully occupied by either a dumbbell or a rare-earth atom, that is, the occupancy of the rare-earth 2b site and that of the Fe 4e site add up to 1 and so do the rare-earth 2c and Fe 4f. Thus, the hexagonal structure can be fully modelled and refinement

TABLE II. The cell parameters, T_c , Al site occupancies for $\text{Ho}_2\text{Fe}_{17-x}\text{Al}_x\text{C}$ and $\text{Ho}_2\text{Fe}_{17-x}\text{Al}_x$. For the hexagonal phase in $\text{Ho}_2\text{Fe}_{17-x}\text{Al}_x$ ($x=1-3$), the Al site occupancies shown are those at equivalent sites of the rhombohedral structure. FIG. 1. Al site occupancies as a function of the Al contents in $Tb_2Fe_{17-x}Al_xC$ (closed symbols) and $Tb_2Fe_{17-x}Al_x$ (open symbols). Squares represent the site occupancies at the Fe(6c), circles for Fe(18f), and triangles for Fe(18h).

FIG. 2. Al site occupancies as a function of the Al contents in $Ho_2Fe_{17-x}Al_xC$.

results are shown in Table II. The Al 6g occupancy in the hexagonal structure is surprising since no Al is found at the cognate 9d site in the rhombohedral structure as in $Ho_2Fe_{17-x}Al_xC$ and $Ho_2Fe_{13}Al_4$.

From the TGA results, the Curie temperatures of the carbides are much higher than those of their uncarbided counterparts. However, within the same series, even though the unit cell volume increases almost linearly with the Al concentration, T_c reaches a maximum between $x=1$ and 2 for $R_2Fe_{17-x}Al_xC$ (Tables I and II), while for $Tb_2Fe_{17-x}Al_x$ (data not yet published) and $Ho_2Fe_{17-x}Al_x$, T_c peaks around $x=3$. Longer bond lengths resulting from the Al substitution and/or C insertion favor the ferromagnetic exchange and thus increase the T_c of the compound. However, as more Al atoms are introduced into the compound, magnetic exchange will be lost. That is why T_c declines with higher Al content. The shifting of the peak of T_c towards the lower Al concentration region with C may be caused by the change in Al site occupancies after the introduction of C or by bond lengths longer than optimum.

Magnetic refinements show that the moments for both the rare-earth and Fe atoms are along the basal plane in samples with and without C. The moments for Tb and Ho atoms couple antiferromagnetically to the Fe sublattice, as expected. The Fe 6c moments have the highest refined values in the Fe sublattice.

High remanence (Sm, Zr)Fe₇N_x + α -Fe nanocomposite magnets through exchange coupling

T. Hidaka, T. Yamamoto, H. Nakamura, and A. Fukuno^{a)}

Materials Research Center, TDK Co., 570-2 Matsugasaki, Minami-Hatori, Narita-shi 286-8588, Japan

We have investigated the influence of α -Fe content on the magnetic properties of (Sm, Zr)Fe₇N_x + α -Fe nanocomposite permanent magnet materials. As α -Fe content increases, the saturation magnetization and the remanence increase while the coercivity decreases monotonously. Also we confirmed the influence of microstructure on magnetic properties. Uniform and fine grain sizes of around 20 nm realized high remanence and high squareness of demagnetizing curve such as $B_r = 9.9$ kG, $H_cJ = 9.1$ kOe, $H_k/H_cJ = 29.9\%$, and $(BH)_{\max} = 17.8$ MGOe. These experimental results agree well with micromagnetic calculations by other researchers. Compaction-molded bonded magnet was prepared by magnetic powders with magnetic properties of $B_r = 9.9$ kG, $H_cJ = 8.2$ kOe, $(BH)_{\max} = 17.5$ MGOe and 2 wt% of epoxy resin. Bonded magnet with a density of 5.91 g/cm³ showed high magnetic properties as follows: $B_r = 7.6$ kG, $H_cJ = 8.4$ kOe, and $(BH)_{\max} = 12.0$ MGOe. © 1998 American Institute of Physics. I. INTRODUCTION

These days, nanocomposite magnets, which consist of magnetically hard and soft phases, have gained much attention because of their high remanence and maximum energy products. So many theoretical and experimental investigations of these magnets have been reported.¹⁻⁸

Isotropic (Sm, Zr)Fe₇N_x + α -Fe nanocomposite magnet, which was developed by the authors through a rapidly quenching method including heat treatment and nitrogeneration, showed magnetic properties high enough for practical use.⁹⁻¹² Also this nanocomposite magnet has shown small deterioration of magnetic properties during pulverization and stable magnetic properties for long time aging at elevated temperature compared with isotropic Nd₂Fe₁₄B single phase-type magnetic powders.¹⁰

In this article we focused on the influence of α -Fe content and also microstructure on the magnetic properties of (Sm, Zr)Fe₇N_x + α -Fe nanocomposite magnets. We also verified the agreement between experimental results and theoretical calculations for nanocomposite magnets.

II. EXPERIMENT

The Sm-Zr-Fe-Co alloys were rapidly solidified by melt spinning onto a Be-Cu roller at a substrate velocity of $V_s = 75$ m/s, under an argon atmosphere. As-quenched flakes were pulverized into particle size of less than 106 μ m. The heat treatment in order to form nanoscaled (Sm, Zr)Fe₇ and α -Fe mixture was carried out over the temperature range of 700–750 °C for 1 h on the overquenched powder samples in an argon atmosphere. After heat treatment, powders were nitrogenated at around 450 °C for 20 h in a nitrogen gas flow atmosphere. The composition of powder samples was checked by fluorescence x-ray method. The nitrogen contents were measured by mass analysis of gas evolved from high-temperature molten alloys. X-ray diffraction analysis

was performed with Cu $K\alpha$ radiation. Transmission electron microscopy (TEM) observation was made with a JOEL JEM-2000FX electron microscope operating at 200 kV. Magnetic properties of powders were measured by using a vibrating sample magnetometer (VSM) with the applied field of 20 kOe after pulse magnetization of 50 kOe. No demagnetization correction has been applied. Resin bonded magnets were fabricated with 2 wt% epoxy resin at a die press pressure of 12 ton/cm² without magnetic field. Magnetic properties of bonded magnets were measured by using a B - H tracer with the applied field of 30 kOe.

III. RESULTS AND DISCUSSION

A. Influence of α -Fe content

In order to investigate the influence of α -Fe content on the magnetic properties of (Sm, Zr)Fe₇N_x + α -Fe nanocomposite magnet, magnetic powder samples with various Sm content were prepared. Their composition is shown in Table I. Nitrogen contents of samples were in a range of 3.7–4.0 wt%. We calculated the α -Fe content for these samples. We did not discriminate Co from Fe, however Co ratio to Fe is around 0.05. A composition of Sm_{10.4}Zr_{3.5}(Fe, Co)_{86.1} has been used for (Sm, Zr)Fe₇ phase with TbCu₇ structure. This compositional analyzed value was obtained by TEM-energy dispersive spectroscopy (EDS) analyses on fine hard phase grains individually.¹² The calculations were performed in the

TABLE I. Composition of magnetic powder samples and calculated phase existence ratio of Fe.

	Sm (at. %)	Zr (at. %)	Fe+Co (at. %)	α -Fe (wt%)	Fe ₈ Zr (wt%)	SmFe ₇ (wt%)
Powder A	8.16	3.40	88.44	16.33	1.68	81.99
Powder B	7.82	3.41	88.77	18.81	2.03	79.16
Powder C	7.79	3.42	88.79	19.00	2.08	78.92
Powder D	7.70	3.42	88.88	19.64	2.16	78.20
Powder E	7.42	3.46	89.12	21.64	2.51	75.85

^{a)}Electronic mail: afukuno@mb1.tdk.co.jp

FIG. 1. X-ray diffraction patterns of magnetic powder samples with various contents of Sm, which were summarized in Table I.

following sequences. First, all of the Sm metal could form (Sm, Zr)Fe₇ phase. Second, the rest of the Zr metal forms Fe₃Zr.¹¹ Finally, the rest of the Fe metal exists as α -Fe phase. The results are given in Table I. X-ray diffraction patterns of these powders are shown in Fig. 1. The peak intensity of α -Fe increased with calculated value of α -Fe content. Dependence of the magnetic properties of these powders on α -Fe content is shown in Fig. 2. As α -Fe content increases, the saturation magnetization and the remanence increase while the coercivity decreases. These phenomena were reported theoretically^{6,7} and experimentally.⁸ Since almost all the micromagnetic calculations applied for the Nd₂Fe₁₄B/Fe₃B or Nd₂Fe₁₄B/ α -Fe system, the calculated value does not coincide, but the tendency agrees well with these results. It was pointed out by Bauer *et al.* that the squareness of the demagnetization curve deteriorated with increasing α -Fe content.⁸ In our research, $(BH)_{\max}$ reached a peak at around 19 wt% of α -Fe, because the same heat treatment condition, including nitrogenation, was applied for sample powders A–E. However, optimization of the heat treatment condition will enable higher magnetic properties, especially for sample powder E.

B. Influence of microstructure

Figure 3 shows bright-field TEM micrographs of powder samples. Figure 3(a) shows uniform and fine grains, which size around 20 nm. Figure 3(b) shows less uniform grains including grain sizes of 60 nm compared with Fig. 3(a). Each magnetic powder showed magnetic properties as follows: (a) $Br=9.9$ kG, $HcJ=9.1$ kOe, $Hk/HcJ=29.9\%$, $(BH)_{\max}=17.8$ MGOe and (b) $Br=9.5$ kG, $HcJ=9.8$ kOe, $Hk/HcJ=22.7\%$, $(BH)_{\max}=15.5$ MGOe, respectively.

We confirmed that fine and uniform microstructure realized higher remanence and Hk/HcJ ratio.

FIG. 2. Dependence of the magnetic properties on α -Fe content.

Theory also predicts^{6,7} that the smaller and more uniform microstructures are essential for higher remanence, especially the Hk/HcJ ratio. The theoretical calculation on the influence of microstructure such as grain sizes and uniformity on magnetic properties agreed well with our experimental results.

C. Magnetic properties of bonded magnet

Compaction-molded bonded magnet made by mixing with a 2 wt% epoxy resin was prepared with magnetic powders with magnetic properties as follows: $Br=9.9$ kG, $HcJ=8.2$ kOe, and $(BH)_{\max}=17.5$ MGOe. The density of bonded magnet made with die press pressure 12 ton/cm² was 5.91 g/cm³. This value was 77% of the powder's density.⁹ Demagnetization curve of bonded magnet is shown in Fig. 4. The bonded magnet showed excellent magnetic properties as follows: $Br=7.6$ kG, $HcJ=8.4$ kOe, and $(BH)_{\max}=12.0$ MGOe. These values are superior to commercially available isotropic Nd₂Fe₁₄B single-phase-type bonded magnet.

IV. CONCLUSIONS

We have investigated the magnetic properties and the microstructures of (Sm, Zr)Fe₇N_x + α -Fe nanocomposite magnets. Observed behavior agreed with theoretical calculations.

FIG. 3. TEM micrographs of magnetic powder samples of magnetic properties as follows: (a) $B_r=9.9$ kG, $H_{cJ}=9.1$ kOe, $H_k/H_{cJ}=29.9\%$, $(BH)_{\max}=17.8$ MGOe and (b) $B_r=9.5$ kG, $H_{cJ}=9.8$ kOe, $H_k/H_{cJ}=22.7\%$, $(BH)_{\max}=15.5$ MGOe.

- (1) When α -Fe content is in the range of 16–22 wt%, increasing α -Fe content, the saturation magnetization, the remanence increase, and the $(BH)_{\max}$ reach a peak while the coercivity decreases monotonously.
- (2) As the microstructure of grains became smaller and more uniform, the magnetic properties of this magnet improved, especially the H_k/H_{cJ} ratio. We also made bonded magnet and evaluated magnetic properties.

FIG. 4. Demagnetization curve of a $(\text{Sm}, \text{Zr})(\text{Fe}, \text{Co})_7\text{N}_x + \alpha\text{-Fe}$ bonded magnet.

- (3) Compaction-molded bonded magnet showed excellent magnetic properties as follows: $B_r=7.6$ kG, $H_{cJ}=8.4$ kOe, and $(BH)_{\max}=12.0$ MGOe.

Effect of Al substitution on the local environments and magnetic properties of partially nitrogenated $(\text{Er}_{0.5}\text{Pr}_{0.5})_2\text{Fe}_{17}$ permanent magnets

V. G. Harris and D. J. Fatemi

U.S. Naval Research Laboratory, Washington, D.C. 20375

K. G. Suresh and K. V. S. Rama Rao

Department of Physics, Indian Institute of Technology, Madras-600 036, India

Extended x-ray absorption fine structure measurements of the Fe K, and Pr and Er L_{III} absorption edges, were carried out to elucidate the relationship between the local structure and magnetism in Al substituted, partially nitrogenated $(\text{Er}_{0.5}\text{Pr}_{0.5})_2\text{Fe}_{17}$ permanent magnets. We find that the nitrogenation acts to dilate both the Fe-Fe and the (Pr,Er)-Fe bonds, thus raising the T_C via a magnetovolume effect. However, nitrogenation of Al-substituted samples acts to decrease the average Fe-Fe bond distance, thus reducing the exchange on the Fe sublattice and lowering T_C relative to the nitrogenated parent compound. This is opposite to the trend measured in systems when N is absent. © 1998 American Institute of Physics. [S0021-8979(98)36011-9]

I. INTRODUCTION

In recent years the magnetovolume enhancement of the magnetic properties in the R_2T_{17} (R : rare earths) permanent magnet compounds has been the subject of much activity. This trend has been spurred largely by the discovery that nitrogenation of these compounds expands the transition metal sublattice and results in a significant increase in the Curie temperature (T_C).¹⁻³ Following in this vein, others have experimented with the substitution of Al and Ga with mixed results.⁴⁻⁸ For example, combining neutron diffraction (ND) and Mossbauer effect (ME) measurements, Long *et al.*⁴ and Yelon *et al.*⁵ have reported compressive studies of the structure and magnetic properties of Al substituted $\text{Nd}_2\text{Fe}_{17}$. This group of researchers have also reported similar styled investigations of the effects of nitrogenation on $\text{Nd}_2\text{Fe}_{17}$ ⁹ and $\text{Pr}_2\text{Fe}_{17}$,¹⁰ and the effects of Ga substitution in the $\text{Nd}_2\text{Fe}_{17}$ system.⁶ Suresh and Rama Rao (SRR) have reported on the magnetic, structural and transport properties of the $(\text{Er}_y\text{Pr}_{1-y})_2\text{Fe}_{17}$ compounds,^{11,12} as well as the effects of Al substitution,⁸ nitrogenation,¹² and the combined use of Al substitution and nitrogenation on these properties.^{7,13}

In the case of $\text{Nd}_2\text{Fe}_{17-x}\text{Al}_x$, Long and Yelon report a near-linear increase in lattice parameters and unit cell volumes with increasing x . A similar result was found by Suresh and Rama Rao in the $(\text{Er}_y\text{Pr}_{1-y})_2\text{Fe}_{17-x}\text{Al}_x$ system. The T_C is reported to increase with increasing Al content for the $\text{Nd}_2\text{Fe}_{17-x}\text{Al}_x$ samples, reaching a maximum near $x=3.5$. For the $(\text{Er}_y\text{Pr}_{1-y})_2\text{Fe}_{17-x}\text{Al}_x$ samples, T_C reaches a maximum for $x=3$, then drops precipitously for $x>4$. The agreement between these results and those of Long *et al.*^{4,9,10} and Yelon *et al.*⁵ suggest that the choice of R plays a minor role in the effect of both Al substitution and nitrogenation.

When Al substitution and nitrogenation are used in conjunction these trends appear to be violated. Taking the case of $(\text{Er}_{0.5}\text{Pr}_{0.5})_2\text{Fe}_{17-x}\text{Al}_x\text{N}_y$, where $y=1$ and $x=0-5$, T_C decreases from the nitrided parent compound with increasing x , ultimately having no effect on the T_C for $x>4$. This result appears to be closely related to the degree of nitrogenation achievable when the parent compound contains Al substituted for Fe. Suresh and Rama Rao report, in agreement with

Buschow *et al.*, the amount of nitrogen one can incorporate into the 2:17 structure is inversely proportional to the amount of Al, with y decreasing with increasing x until $y=0$ for $x=6$.⁷

In this article, we explore the effects of Al substitution on the local structure and magnetism of the permanent magnet, $(\text{Er}_{0.5}\text{Pr}_{0.5})_2\text{Fe}_{17-x}\text{Al}_x\text{N}_y$.

II. EXPERIMENT

The compounds were prepared by arc melting elements of 99.9% purity for Pr and Er and 99.99% purity for Fe and Al under dynamic positive pressure of Ar gas. The melted ingots were then homogenized at 900 °C for 7 days. The nitrogenation was carried out using a high pressure apparatus that was specifically designed for this purpose. The degree of nitrogenation was measured by monitoring the pressure drop in the reactor due to absorption by the sample. This apparatus is described in detail in Ref. 12.

Powder x-ray diffraction, using a fixed anode Co target, verified that all samples were nearly pure phase, with some having trace amounts of α -Fe. For the range of Al substitution that we study here, $0 \leq x \leq 3$, the a and c parameters are measured to increase $\sim 1\%$.

Magnetization measurements were carried out using a PAR vibrating sample magnetometer in the temperature range of 28–800 K, and Mossbauer effect (ME) measurements using a conventional fixed acceleration spectrometer with a 20 mCi ^{57}Co source embedded in a Rh matrix over a temperature range of 18–700 K. We direct the reader to Refs. 7 and 13 for details of the long-range-structure and magnetic properties of these samples.

In preparation of x-ray absorption measurements the powder samples were spread onto 3M Scotch Magic Tape™. Multiple layers of these powdered tapes were stacked in order to tailor the amount of absorption by the sample at the absorption edge being measured. This was done so as to optimize the signal to noise and to improve the uniformity of the sample exposed to the radiation. The x-ray absorption coefficient, in the range of the Fe K and Pr and Er L_{III} ab-

sorption edges, were measured in transmission mode using the X23B beamline¹⁴ at the National Synchrotron Light Source (Brookhaven National Laboratory).

Following the procedural steps outlined in Ref. 15, the extended fine structure above the absorption edge was isolated, normalized to the edge energy and step height, and converted to photoelectron wave vector space (k). In k space, a cubic spline background was fit and removed from the data to minimize the nonoscillatory atomic background curvature. These data were then Fourier transformed (FT) to radial coordinates for examination of the local environments around the absorbing atoms. In this form the FT peaks are offset from their true bond distances by an electronic phase shift.

Quantitative analysis of the local environment around Fe, Pr, and Er was performed by Fourier-filtering the NN peak in the FT EXAFS spectra and least squares fitting these data with simulated single-scattering EXAFS data generated using the FEFF (vs 6) codes of Rehr *et al.*¹⁶ This type analysis provides a quantitative measure of the nearest neighbor (NN) distance (i.e., bond lengths), Debye-Waller coefficients (DWCs) (i.e., thermal and static atomic disorder), and the coordination number, i.e., the total number of atoms contributing to the local coordination sphere around the absorbing atoms.

III. RESULTS AND DISCUSSION

We are limited by space considerations and provide only EXAFS analysis of the Fe K and Pr L_{III} EXAFS. The Er L_{III} analysis is omitted here and will be presented elsewhere.

Figure 1 is a plot of the FT Fe EXAFS collected from the Al-substituted and nitrided samples, together with data for the parent compound. These data have been analyzed using identical background removal procedures and FT parameters, and are plotted on the same axes to allow for direct comparison. The x axis is limited to $1.0 \text{ \AA} < r < 5.0 \text{ \AA}$ to allow a clear inspection of the NN region. Samples having $x=0, y=1$; $x=0, y=0$; and $x=3, y=1$; are plotted with error bars that were calculated to reflect both the statistical uncertainty and the error introduced to the data from the procedural steps prior to and including the Fourier transformation. The inset panel depicts a plot of the average Fe-Fe/Al bond distance (henceforth denoted $\langle r \rangle_{\text{Fe-Fe/Al}}$) and the average Fe-Fe/Al DWC (henceforth denoted $\langle \text{DWC} \rangle_{\text{Fe-Fe/Al}}$) calculated for the atoms contributing to the NN peak as a function of x . Values coinciding to the parent compound are to provide a reference baseline.

In the FT data of Fig. 1 we see that significant structural change occurs around the Fe atoms with the substitution of Al. These are most visible as changes in the Fourier peak amplitudes appearing over $2 \text{ \AA} < r < 5 \text{ \AA}$ and a shift in the position of the NN Peak. Because the NN peak of Fe is dominated by other Fe and Al atoms that are distributed on 4 inequivalent sites (i.e., 6c, 9d, 18f, 18h) we opt to describe the environment as an average Fe-Fe/Al bond unless otherwise specified. This simplification reduces the number of adjustable parameters in our fitting analysis from as many as 12 to no more than 3.

FIG. 1. Fourier transformed Fe K EXAFS for $(\text{Er}_{0.5}\text{Pr}_{0.5})_2\text{Fe}_{17-x}\text{Al}_x\text{N}_y$ where $x=0, 1, 2$ and 3 and $y=0, 1$. A k^3 -weighting was applied to a k -range of 2.3 – 13.25 \AA^{-1} . The inset panel depicts a plot of the percent change in the calculated average Fe-Fe/Al bond distance and the Debye-Waller coefficient for the Fe coordination sphere relative to the same in the parent compound. These data were deduced from a least-squares fitting of a FF r range indicated by the arrows.

Upon nitrogenation the $\langle r \rangle_{\text{Fe-Fe/Al}}$ increases 0.9% from that of the parent compound. This result is a direct measurement of the dilation of the Fe coordination sphere which reflects the expansion of the Fe sublattice and accounts for the widely reported increase in Curie temperature experienced when the 2:17s are nitrided. With the substitution of Al we observe that $\langle r \rangle_{\text{Fe-Fe/Al}}$ decreases abruptly (-0.6%), plateaus, and then continues its decrease. Although, others have reported a unit cell volume increase with the substitution of small amounts of Al ($x < 4$) (sans N),^{4,8} we observe that in partially nitrided samples, the Al acts to contract the Fe coordination sphere relative to the nitrided baseline. This contraction is no doubt responsible for the measured decrease in Curie temperature in these compounds, and is consistent with the ME results of Suresh and Rama Rao¹³ who found that the T_C and the HFF of all Fe sites reduce with increased Al content for these samples.

The $\langle \text{DWC} \rangle_{\text{Fe-Fe/Al}}$ increases with increased Al content for $0 < x < 2$, and experiences a relative decrease for $x=3$. Because it is reasonable for one to assume that the thermal component to the DWC does not change appreciably with x , this trend largely reflects the static displacements of atoms about their mean bond distance. The abrupt reversal in the DWC for $x=3$, and the corresponding reduction in the $\langle r \rangle_{\text{Fe-Fe/Al}}$, signals increased ordering and a closer packing of atoms around the Fe atoms for $x=3$.

In separate fitting analyses, the Fe-Al correlations were fit simultaneously with the Fe-Fe correlations in the same manner as described in Sec. II B. These fitting results (not shown) indicate that the Fe-Al bond undergoes an abrupt decrease for $x=3$. The most plausible explanation of this result and the behavior of the average Fe environment is a

redistribution of Al atoms to sites having a closer NN distance.

Long *et al.*⁴ report that Al atoms preferentially reside in the 18h site for low x (i.e., $x < 4$), and prefer the 6c and 18f sites for higher x (i.e., $x > 6$). Because the 18h sites have a NN distance of ~ 2.576 Å, while the 6c sites have a longer average NN distance of ~ 2.675 Å, one would expect a slight dilation of the Fe coordination sphere.¹⁷ Instead we measure a distinct contraction of the Fe coordination sphere, suggesting that the behavior of the Al site filling is significantly effected by the presence of the N ions. Our measured contraction is more consistent with a redistribution of Al atoms to the 9d sites although we cannot rule out some other electronic interaction which might facilitate a contracted bond distance without the need for redistribution of sites.

Figure 2 is plots of FT Pr L_{III} EXAFS data for all samples. Because of the onset of the Fe K transition at 7112 eV, the Pr L_{III} extended fine structure is terminated at approximately 11 Å^{-1} . Data for samples $x=0, y=0$; $x=0, y=1$; and $x=3, y=1$ are plotted with error bars. Like the Fe data of Fig. 1, we see that nitrogenation acts to increase the radius of the Pr coordination sphere by 1.7%. The $\langle \text{DWC} \rangle_{\text{Pr-Fe/Al}}$ increases 24%, compared to the modest increases of $<1\%$ for the Fe environment. This effect is fully consistent with what one would expect if the N ions were to occupy sites in close proximity to the R sites creating static strain fields between the R and Fe/Al NN atoms. This observation is consistent with the results of Capehart, Mishra, and Pinkerton who performed EXAFS studies to determine the site occupation of the N interstitials, and concluded that they reside on the 9e sites.¹⁸

With Al substitution, the Pr environment experiences a steady increase in the atomic disorder as evidenced by the increase in $\langle \text{DWC} \rangle_{\text{Pr-Fe/Al}}$. In addition, the $\langle r \rangle_{\text{Pr-Fe/Al}}$ increases 1.0% for the range $1 < x < 3$, then experiences a small dip for $x=3$. However, the FT of the $x=3$ data clearly shows a large asymmetry in the NN environment indicating at least a bimodal distribution of bonds. Because we fit this range of data with a single "average" bond length a physical interpretation of the fitting results may not be tenable. Alternatively, the appearance of this high- r asymmetry in the NN region is consistent with a preferential filling of Al on the 9d sites which have the largest Pr-Fe/Al bond distance, 3.342 Å. This result alone would not be compelling save for the trend in the Fe EXAFS data which supports a redistribution of Al atoms to the 9d sites as a source of the measured contraction of the Fe coordination sphere.

In summary, we find the act of nitriding the $(\text{Er}_{0.5}\text{Pr}_{0.5})_2\text{Fe}_{17}$ structure is to dilate both the Fe and Pr coordination spheres leading to an increase in the T_C via a positive magnetovolume effect on the Fe sublattice. Second, we report that in the concurrent use of Al substitution and partial nitrogenation acts to reduce the radius of the Fe coordination sphere thus reducing the Fe-Fe exchange and lowering T_C .

We observe local structural changes around Fe and Pr with Al substitution that suggest either a preferential redistribution of Al atoms to the 9d sites for $x \geq 3$, or an electronic interaction that facilitates a contracted bonding ar-

FIG. 2. Fourier transformed Pr L_{III} EXAFS for $(\text{Er}_{0.5}\text{Pr}_{0.5})_2\text{Fe}_{17-x}\text{Al}_x\text{N}_y$, where $x=0, 1, 2$ and 3 and $y=0, 1$. A k^3 -weighting was applied to a k range of 2.3 – 10.9 Å^{-1} . The inset panel depicts a plot of the calculated average Pr-Fe/Al bond distance and the Debye-Waller coefficient for the Pr coordination sphere relative to the same in the parent compound. These data were deduced from a least-squares fitting of a FF r range indicated by the arrows.

range for Fe and a dilated bonding arrangement for Pr. This result suggest that the presence of N in the unit cell alters the site filling characteristics of Al in this compound.

Zhenjie Zhao and Fashen Li

Department of Physics, Lanzhou University, Lanzhou Gansu 730000, People's Republic of China

Magnetic and ^{57}Fe Mössbauer spectra measurements were carried out to study the interstitial nitrogen atom effects in the $\text{NdFe}_{10.5}\text{V}_{1.5}\text{N}_x$ ($0 \leq x \leq 2.1$) compounds. It is found that saturation magnetization, magnetocrystalline anisotropy, hyperfine fields, and isomer shifts of $\text{NdFe}_{10.5}\text{V}_{1.5}\text{N}_x$ are strongly enhanced upon nitrogenation, due to magneto-volume effects and chemical bonding effects of nitrogen atoms. On the basis of the variation of isomer shifts and hyperfine fields as a function of nitrogen concentration, and by using a set of phenomenological formulas, the contributions of magneto-volume effect and the chemical bonding effect to the hyperfine parameters are successfully separated. The pure magneto-volume effect and the chemical bonding effect of the nitrogen atoms will give a positive contribution to the average hyperfine fields and isomer shifts of the Fe atoms in the $\text{NdFe}_{10.5}\text{V}_{1.5}\text{N}_x$ nitrides. © 1998 American Institute of Physics. I. INTRODUCTION

Magnetic properties of ThMn_{12} -type Fe-rich ternary intermetallic compounds $\text{RFe}_{12-x}\text{M}_x$, in which R is rare earth and M is Ti, V, Cr, Mo, Si, Mn, W and Al, can be considerably improved by introducing C or N atoms in the interstitial sites.^{1,2} Due to the interstitial nitrogen atom effect, $\text{NdFe}_{12-x}\text{M}_x\text{N}_y$ nitrides are considered as a candidate for permanent magnetic applications. The magnetic properties of the $\text{NdFe}_{12-x}\text{M}_x\text{N}_y$ vary with the third element M . Among them, $\text{NdFe}_{12-x}\text{V}_x\text{N}_y$ possesses a higher Curie temperature and a larger saturation magnetization (M_s). Therefore, the effects of the interstitial atoms on the magnetic properties of $\text{RFe}_{12-x}\text{V}_x\text{N}_y$ compounds are a topic of great interest from the point of view of theoretical studies or in the technical applications.

The effects of C or N atoms in the interstitial sites could be decomposed into two parts: magneto-volume effect and chemical bonding effect. The theoretical effort to distinguish the influences of these two effects on the Fe moments has been made on the basis of calculations of local magnetic moments for different Fe sites in $\text{YFe}_{11}\text{TiN}^{3,4}$ and $\text{R}_2\text{Fe}_{17}\text{Z}_3$ ($R = \text{Y, Gd}, Z = \text{C, N}$)^{5,6} by means of the local spin density approximation and linear muffin tin orbital theory. However, up to date, experimental investigations on them are rarely found in literature. Li *et al.* have investigated, by high pressure Mössbauer effect, the interstitial atoms effects in $\text{Gd}_2\text{Fe}_{17}\text{C}_x$.⁷ Since the high pressure Mössbauer measurements are not easy to carry out, herein we try to experimentally separate these two effects from conventional Mössbauer measurements. For this purpose, Mössbauer spectra of $\text{NdFe}_{10.5}\text{V}_{1.5}\text{N}_x$ with various nitrogen concentration were measured. And by using a set of phenomenological formulas, the contributions of magneto-volume effect and the chemical

bonding effect to the hyperfine parameters are successfully separated.

II. EXPERIMENTAL METHODS

Parent alloys were prepared by arc melting of 99.9% pure metals in an argon atmosphere, followed by a heat treatment at 900 °C for three days. The homogenized ingots were pulverized into fine powders with an average size of about 15 μm . Nitrogenation was performed by heating powders in purified nitrogen gas at atmospheric pressure at 500–600 °C for 1–8 h. X-ray diffraction (XRD) and chemical analysis were made to determine the structure and the nitrogen content. The samples of cylindrical shape ($\phi 3 \times 4$ mm) were aligned in a magnetic field of 10 kOe and fixed in epoxy resin. The magnetization curves of aligned samples were measured by a vibrating sample magnetometer with a field of up to 20 kOe at room temperature. ^{57}Fe Mössbauer spectra were collected using a conventional constant acceleration spectrometer with a 20 m Ci source of ^{57}Co in rhodium at room temperature.

III. RESULTS AND DISCUSSIONS

Figure 1 shows the $\text{CuK}\alpha$ XRD patterns of the $\text{NdFe}_{10.5}\text{V}_{1.5}$ and $\text{NdFe}_{10.5}\text{V}_{1.5}\text{N}_x$. The XRD patterns show that alloys before and after nitrogenation are of ThMn_{12} -type tetragonal structure. It is evident that the diffraction peaks of $\text{NdFe}_{10.5}\text{V}_{1.5}\text{N}_x$ shift to lower angle, indicating that the lattice expands after nitrogenation and the nitrogen atoms mainly occupy interstitial sites. The unit cell volumes V and relative change in unit cell volume upon nitrogenation, $\delta V/V$, are summarized in Table I. It can be seen from the table that the unit cell volume of $\text{NdFe}_{10.5}\text{V}_{1.5}\text{N}_x$ increases with nitrogen content. This indicates that the higher nitrogenation concentration it is, the more nitrogen atoms it will enter into the interstitial sites. A number of neutron diffraction studies on

^{a)}Electronic mail: jbyang@ibm320h.phy.pku.edu.cn

FIG. 1. X-ray diffraction patterns of the $\text{NdFe}_{10.5}\text{V}_{1.5}\text{N}_x$ and $\text{NdFe}_{10.5}\text{V}_{1.5}\text{N}_x$.

$\text{YTiFe}_{11}\text{N}_x$, $\text{YFe}_{10}\text{V}_2\text{N}_x$, and $\text{YFe}_{10}\text{Mo}_2\text{N}_x$ or $\text{YFe}_{11}\text{MoN}_x$ have been made.^{8,9} All these studies lead to the same conclusion that nitrogen atoms were found to occupy the octahedral $2b$ interstitial sites. Accordingly, full occupation of these $2b$ sites in the case of $\text{NdFe}_{10.5}\text{V}_{1.5}$ nitrides leads to a composition as $\text{NdFe}_{10.5}\text{V}_{1.5}\text{N}_{1.0}$. However, the experimentally estimated nitrogen content x ranges from 0 to as large as 2.1, which is much more than the theoretical value of one nitrogen atom per formula unit. This fact suggests that the nominal nitrogen content is much larger than the nitrogen occupancy number on the $2b$ site. A neutron diffraction study to detect the location of additional nitrogen atoms in these compounds is on course.

The measured values of saturation magnetization and anisotropy fields H_a of $\text{NdFe}_{10.5}\text{V}_{1.5}\text{N}_x$ are summarized in Table I. It is evident that a significant dependence of nitrogen content on saturation magnetization and magnetocrystalline anisotropy of $\text{NdFe}_{10.5}\text{V}_{1.5}\text{N}_x$ is observed. The increase of the saturation magnetization is a result of the magneto-volume effect and the chemical bonding effect, which increases the Fe magnetic moments upon nitrogenation. It is clearly that the chemical bonding effect between N and Nd changes the sign of the second-order crystal field parameter of Nd and results in c -axis anisotropy in the nitrides.¹⁰ However, it is difficult to experimentally separate the influences of magneto-volume effect and chemical bonding effect on the Fe mag-

1.69	360.0	4.8	129.2	9.9
2.08	362.0	5.1	131.9	10.3

FIG. 2. Mössbauer spectra of $\text{NdFe}_{10.5}\text{V}_{1.5}\text{N}_x$ at room temperature.

netic moments in the nitrides. Accordingly, a Mössbauer study on these compounds was carried out.

Representative Mössbauer spectra of $\text{NdFe}_{10.5}\text{V}_{1.5}\text{N}_x$ measured at room temperature are shown in Fig. 2. The Mössbauer spectra of the $\text{NdFe}_{10.5}\text{V}_{1.5}$ and their nitrides have been fitted to eleven subspectra with relative intensities calculated by Denissen *et al.*¹¹ and Sinnemann *et al.*¹² for similar compounds with the ThMn_{12} structure. By assuming the V goes randomly to the $8i$ sites, the probability $P_n(m)$ of finding m vanadium atoms in a shell of n $8i$ nearest neighbors is given by the binomial distribution

$$P_n(m) = \frac{n!}{m!(n-m)!} x^m (1-x)^{n-m}, \quad (1)$$

where x is the concentration of vanadium atom. The relative intensities of the subspectra were given in Table II. On the basis of these probabilities, the subspectra with intensities less than 3% were neglected. This led to a maximum of 11 subspectra for fitting a whole Mössbauer spectrum. The hyperfine fields (B_{hf}) at three Fe sites take the order $B_{\text{hf}}(8i) > B_{\text{hf}}(8j) > B_{\text{hf}}(8f)$, according to the analyses and opinions.¹¹⁻¹⁵

The fitted hyperfine parameters are listed in Table III. The average hyperfine field ($\overline{B_{\text{hf}}}$) increases monotonously with nitrogen content. This is due to the magneto-volume effect and chemical bonding effect of nitrogen atoms. The average isomer shift (IS) of $\text{NdFe}_{10.5}\text{V}_{1.5}\text{N}_x$ also steadily increases with the nitrogen content x .

TABLE II. Calculated intensities, (%) for the different subspectra of $\text{NdFe}_{10.5}\text{V}_{1.5}\text{N}_x$.

Fe sites	Fe nearest neighbors							
	13	12	11	10	9	8	7	6
$8i$	2.3	6.8	8.2	4.9	1.5	0.2		
$8j$				5.8	14.0	12.6	5.0	0.8
$8f$				5.8	14.0	12.6	5.0	0.8

TABLE III. The hyperfine parameters of NdFe_{10.5}V_{1.5}N_x at room temperature. The isomer shifts are relative to α -Fe at room temperature. The data errors were given in parentheses.

x	$\overline{B}_{\text{hf}}(\text{T})$	$\overline{\text{IS}}(\text{mm/s})$
0.00	22.8(5)	-0.123(3)
0.56	25.1	-0.008
1.03	27.9	0.044
1.56	29.1	0.073
1.69	32.5	0.081
2.08	33.4	0.095

The following two effects are responsible for the changes of the hyperfine parameters upon nitrogenation: (1) the magneto-volume effect due to the increase of the unit cell volume upon nitrogenation, (2) the chemical effect mainly due to charge transfer and hybridization between the interstitial atoms and the neighboring Fe atoms. According to the suggestion of Wagner and Wortmann for the metal hydrides,¹⁶ these two effects can be separated with a sets of phenomenological equations

$$\frac{d \ln \overline{B}_{\text{hf}}}{dn} = \left(\frac{\partial \ln \overline{B}_{\text{hf}}}{\partial \ln V} \right)_n \frac{d(\ln V)}{dn} + \left(\frac{\partial \ln \overline{B}_{\text{hf}}}{\partial n} \right)_V, \quad (2)$$

$$\frac{d \overline{\text{IS}}}{dn} = \left(\frac{\partial \overline{\text{IS}}}{\partial \ln V} \right)_n \frac{d(\ln V)}{dn} + \left(\frac{\partial \overline{\text{IS}}}{\partial n} \right)_V, \quad (3)$$

where the \overline{B}_{hf} and $\overline{\text{IS}}$ are the average hyperfine fields and isomer shifts of Fe atoms in the RFe_{10.5}V_{1.5}N_x, V is the unit cell volume of NdFe_{10.5}V_{1.5}N_x, and n is a ratio of nitrogen atoms to the other metal atoms in a formula unit. In Eqs. (2) and (3), the first term gives the contribution of the magneto-volume effect and the last term is the contribution of the chemical bonding effect.

Generally, $(\partial \ln \overline{B}_{\text{hf}} / \partial \ln V)_n$ and $(\partial \overline{\text{IS}} / \partial \ln V)_n$ are derived from the high pressure Mössbauer measurements. In spite of nonlinear dependence of the IS and B_{hf} at Fe sites on V and n , in the first order of approximation, we supposed that $(\partial \ln \overline{B}_{\text{hf}} / \partial \ln V)_n = A$, $(\partial \ln \overline{B}_{\text{hf}} / \partial n)_V = B$, $(\partial \overline{\text{IS}} / \partial \ln V)_n = C$, and $(\partial \overline{\text{IS}} / \partial n)_V = D$ are constant in these compounds, and quantitatively estimate the magneto-volume effect and chemical bonding effect. Then Eqs. (2) and (3) can be written as

$$d \ln \overline{B}_{\text{hf}} = A * d(\ln V) + B * dn, \quad (4)$$

$$d \overline{\text{IS}} = C * d(\ln V) + D * dn. \quad (5)$$

Because we have prepared a series of samples with various nitrogen concentration and unit cell volume, the values of A , B , C , and D can be obtained through solving Eqs. (4) and (5). The values of $d \ln V / dV$ can be obtained from the x-ray diffraction measurements. By using values of the $d \ln \overline{B}_{\text{hf}}$, $d \overline{\text{IS}}$, $d \ln V$, and dn calculated from Table III and Table I, and solving the Eqs. (4) and (5) by using least-

squares method, one derives the values of $A=6.8$ T and $B=0.7$ T, $C=1.80$ mm/s, and $D=0.04$ mm/s, respectively.

It is noticed from the values of A and B that both magneto-volume effect and chemical bonding effect will increase the hyperfine field. This is in good agreement with the conclusion of the band calculation³ that nitrogen atoms will enhance the Fe moments not only through lattice expansion but also by changing the electronic bonding nature. The increase of the hyperfine field through magneto-volume effect is due to a decrease in Fe-Fe overlap. The formation of tight covalent bonding between neodymium and nitrogen atoms releases the Fe atoms from the bonding with neodymium atoms and then promotes the exchange splitting of the Fe atoms, which will further increase the magnetic moments and hyperfine fields of Fe atoms due to chemical bonding effect. The results of isomer shifts indicate that chemical bonding effect and magneto-volume effect will give rise to an increase of isomer shifts. It is easy to understand that the volume expansion will decrease s electron density in the nuclear sites which gives an increase to the isomer shifts. The value $(\partial \overline{\text{IS}} / \partial \ln V) = 1.80$ mm/s is closed to that of NdFe_{12-x}Mo_xN_{0.9} (2.0 mm/s).¹⁴ The chemical bonding effect of the nitrogen atoms promotes the mobility of the electrons, and then in turn decreases the s -like charge density at Fe nucleus, so that isomer shifts at Fe sites increase.

A study of nitrogenation of a $\text{NdFe}_{12-x}\text{Mo}_x$ compound by *in situ* neutron powder diffraction

C.-K. Loong^{a)} and S. M. Short

Argonne National Laboratory, Argonne, Illinois 60439

J. Lin and Y. Ding

Department of Materials Chemistry, Peking University, Beijing 100871, China

The effects on the crystal lattice of a $\text{NdFe}_{12-x}\text{Mo}_x$ ($x \approx 1.7$) during controlled nitrogenation over the 25–600 °C temperature range were studied by neutron powder diffraction. Prior to nitrogenation the sample contained a major phase of $\text{NdFe}_{10.3}\text{Mo}_{1.7}$ and a minor phase (~ 12 vol %) of bcc-Fe. The sample inside the furnace was connected to a closed volume of ultrapure nitrogen gas while neutron data were collected over regular time intervals during sequential heating. Substantial nitrogen absorption occurred between 500 and 600 °C. During the nitrogenation process the $\text{NdFe}_{12-x}\text{Mo}_x\text{N}_y$ lattice expanded while the bcc-Fe lattice contracted. An increasing decomposition of the compound into bcc-Fe at 600 °C was observed. The average size of the $\text{NdFe}_{12-x}\text{Mo}_x\text{N}_y$ crystalline grains decreased starting at ~ 300 °C, reaching a minimum at ~ 500 °C and then increased markedly at higher temperatures. The development of lattice strains, on the other hand, showed an opposite trend, i.e., a maximum at 500 °C. © 1998 American Institute of Physics. [S0021-8979(98)29811-2]

I. INTRODUCTION

Interstitial introduction of nonmetallic atoms such as N, C, or B into rare-earth (R) transition-metal (TM) compounds is one of the effective methods for fabricating new hard magnetic materials with improved properties. The method of gas-phase interstitial modification (GIM) has been applied to two families of R-TM intermetallics, the 2:17 and the 1:12 systems, with $\text{Sm}_2\text{Fe}_{17}\text{N}_y$ and $\text{NdFe}_{12-x}\text{Mo}_x\text{N}_y$ being the leading targeted materials. Depending on the dissociation energy of the gas molecules, the strain-stress conditions of the lattice, and the nature of the gas-lattice interaction, these metastable phases of nitrides are formed within a relatively narrow temperature window. A considerable amount of investigations of the reaction mechanism and phase formation have been carried out for the $\text{Sm}_2\text{Fe}_{17}\text{N}_y$ compounds using the GIM method.^{1–5} The corresponding behavior of the $\text{NdFe}_{12-x}\text{Mo}_x\text{N}_y$ system, on the other hand, has not been well characterized.

The crystal structure of the parent compounds of the 1:12 family, $\text{RFe}_{12-x}\text{M}_x$ ($\text{M}=\text{Mo}, \text{Ti}, \text{V}, \text{Cr}, \text{W}, \text{or Si}$) is based on the ThMn_{12} -type body-centered tetragonal structure (space group $I4/mmm$, 2 formula units per cell).⁶ The inclusion of M atoms is essential to the stabilization of the ThMn_{12} structure. In the case of $\text{RFe}_{10}\text{Mo}_2$, the R, and Fe atoms occupy the $2a$ and $(8i, 8j, 8f)$ sites, respectively, and the Mo atoms preferably occupy the $8i$ site. Upon nitrogenation the lattice expands, causing a narrowing of the Fe $3d$ band and thereby a larger saturation moment and higher Curie temperature.⁷ Since the N atoms occupy the $2b$ site which is in close proximity to the R atoms, the crystalline electric fields surrounding the R atoms are modified significantly.⁸ In $\text{RFe}_{12-x}\text{Mo}_x\text{N}_y$ the magnetic anisotropy changes from planar

(for $y=0$) to uniaxial along the c direction. The magnetic properties of $\text{RFe}_{12-x}\text{Mo}_x$ and its $\text{RFe}_{12-x}\text{Mo}_x\text{N}_y$ ($y < 0 \leq 1$) have been investigated by many workers.^{8–17}

As the formation of $\text{RFe}_{12-x}\text{M}_x\text{N}_y$ occurs within a rather limited composition range ($1.5 < x < 2.5$ and $0 < y < 1$), many authors reported the observation of impurity phases, most often α -Fe, in the parent and/or nitrogenated materials.^{9–14,16,17} This difficulty has prompted an attempt in synthesizing $\text{NdFe}_{10}\text{Mo}_2$ using a polymer-network gel process.¹⁸ Concerns about the stability of the 2:17 compounds have led to numerous investigations of the MIG process.^{1–5,19} During the nitrogenation of $\text{Sm}_2\text{Fe}_{17}$, the diffusion of nitrogen into the bulk of particles via extended defects on the surfaces, the development of lattice strains, and the decomposition of the materials at high temperatures were studied by several workers.^{1,3,5} Similar studies of the $\text{NdFe}_{12-x}\text{Mo}_x\text{N}_y$ system, to the best of our knowledge, have not been reported. In this article, we present the results of an *in situ* neutron-diffraction study of the nitrogenation process of a $\text{NdFe}_{10.3}\text{Mo}_{1.7}$ compound.

II. EXPERIMENTAL DETAILS: RESULTS AND DISCUSSION

The $\text{NdFe}_{10.3}\text{Mo}_{1.7}$ sample was prepared by arc melting under a purified argon atmosphere from the elemental materials of at least 99% purity, followed by vacuum annealing at 950 °C for a week. After cooling, the sample was ground into a powder with particle size, examined by optical microscopy, about 20–30 μm . X-ray diffraction analysis, carried out on a Rigaku D/Max-2000 diffractometer, showed the ThMn_{12} -type structure of the $\text{NdFe}_{10.3}\text{Mo}_{1.7}$ compound and a small amount of bcc α -Fe.

The neutron diffraction experiment was performed using a time-of-flight powder diffractometer (SEPD) at the Intense

^{a)}Electronic mail: ckloong@anl.gov

Pulsed Neutron Source of Argonne National Laboratory. The powder (~ 20 g) was held inside a cylindrical, thin-wall vanadium tube. Four layers of very fine stainless-steel screens were laid at the open bottom and vent holes were left at the top of the tube to allow permeation of N_2 gas. The sample tube was placed inside an insert of the furnace which was connected to a manifold of a gas handling apparatus filled with 1 ℓ 99.999% pure nitrogen gas at 1 atm pressure and room temperature. After repeated purging, the nitrogen gas was expanded into the furnace insert, and the pressure was monitored throughout the experiment. The data were collected by detectors situated at mean scattering angles of $\pm 90^\circ$ for which a resolution of $\Delta d/d = 0.5\%$ can be achieved (d is the atomic plane spacing). By virtue of the highly collimated neutron entrance and exit in a 90° -scattering geometry and the negligible neutron coherent scattering amplitude of vanadium, Bragg-scattering intensity solely from the sample was recorded. The sample temperature, monitored by thermocouples above and below the sample, were controlled at a selected temperature to within 10°C in all runs. The diffraction data were collected for 1 h at a constant temperature as the temperature was raised stepwise from room temperature to $\sim 600^\circ\text{C}$. At about 450, 500, 550, and 600°C several 1 h runs were made in order to study the kinetics of N_2 absorption. No attempt was made to wait until the saturated absorption before raising to the next temperature. Each data set analyzed by the Rietveld refinement technique using the generalized structural analysis system (GSAS) computer code,^{20,21} therefore represents the lattice response averaged over the 1 h period at a temperature during nitrogenation.

In order to obtain information about the thermal expansion of the un-nitrogenated sample, measurements were also performed on a fresh powder from room temperatures to 600°C under a vacuum environment.

Figure 1 shows a portion of the diffraction pattern typical of runs at 134 and 596°C . The fresh sample prior to nitrogenation contains a major phase of $\text{NdFe}_{10.3}\text{Mo}_{1.7}$ and a minor phase (~ 12 vol %) of bcc α -Fe. As the temperature increases from 24 to $\sim 450^\circ\text{C}$, the unit-cell volume of both phases increase at a normal rate as expected from thermal expansion. At $\sim 500^\circ\text{C}$, however, the salient drop of the nitrogen gas pressure in conjunction with a shift of the d spacing and the intensities of the Bragg reflections indicate clearly the formation of nitride $\text{NdFe}_{10.3}\text{Mo}_{1.7}\text{N}_y$. The weighted R factors of the two-phase structural refinements varies from $\sim 8\%$ at room temperature to $\sim 12\%$ at 600°C . Figure 2 shows the unit-cell volume of the nitride and α -Fe phases as well as the $2b$ site occupancy of nitrogen and the α -Fe volume fraction as a function of temperature. By comparing with the unit-cell volumes of the un-nitrogenated phases [Fig. 2(a)], it can be seen that over a 7 h period at 500°C the unit cell of $\text{NdFe}_{10.3}\text{Mo}_{1.7}\text{N}_y$ expands continuously as more N atoms diffuse into the lattice whereas the bcc unit cell of the α -Fe lattice contracts. Furthermore, since the $2b$ site is located at the midpoint of two R atoms along the c axis, the unit-cell expansion of the nitride is highly anisotropic, i.e., larger in the c direction. The same behavior occurs at 500 and 600°C . Meanwhile, as y increases, the

FIG. 1. The Rietveld profile fits of diffraction data for the $\text{NdFe}_{10.3}\text{Mo}_{1.7}\text{N}_y$ (+ α -Fe) sample at 134 and 596°C . The dots are the observed, background-subtracted intensities. The solid lines represent the calculated intensities. Tick marks of top and bottom rows indicate the positions of the Bragg reflections for α -Fe and $\text{NdFe}_{10.3}\text{Mo}_{1.7}\text{N}_y$ phases, respectively. Differences between the observed and calculated intensities are shown at the bottom of each panel.

volume fraction of α -Fe also increases from 15% at 400°C to 25% in the last run at 600°C . Therefore, as more N atoms are incorporated into the Nd-Fe-Mo compound, the lattice expands and exerts compressive stresses on the α -Fe domains in the sample. At increasing temperatures the material becomes less stable, as can be seen from the accelerated precipitation of α -Fe phase.

Information regarding the average crystalline grain size and the lattice microstrains of the nitride can be obtained from the Rietveld refinements of the diffraction data.²⁰ As shown in Fig. 3 the size and strains of the Nd-Fe-Mo domains do not change significantly up to about 300°C . Above $\sim 300^\circ\text{C}$ the coherency of the crystalline domains decreases rapidly, as indicated by the reduction of average grain size and the rise of lattice strains. These effects are largest at about 500°C where nitrogen diffusion rate is near a maximum (see Fig. 2), and the behavior reverses precipitously, i.e., increasing grain size and reducing strains, between 500 and 600°C . The signals from the α -Fe phase are too weak to warrant similar grain-size and strain analysis. These results enable us to speculate the following scenario. Below 300°C nitrogen diffusion into the sample is minimal, perhaps lacking the thermal and gas-solid interaction energies to activate the dissociation of nitrogen molecules. At $\sim 300^\circ\text{C}$ N atoms begin to diffuse and interact with the atoms on the intergranular boundaries of the $\text{NdFe}_{10.3}\text{Mo}_{1.7}$ particles. It is not until about 400°C when N atoms interact with the Fe (and Nd) atoms in the bulk of the particles, forming chemical bonds through hybridization of the N-2p and Fe-3d states.²² Presumably N diffuses into the bulk through defect structures extended inward from the surface while imposing ex-

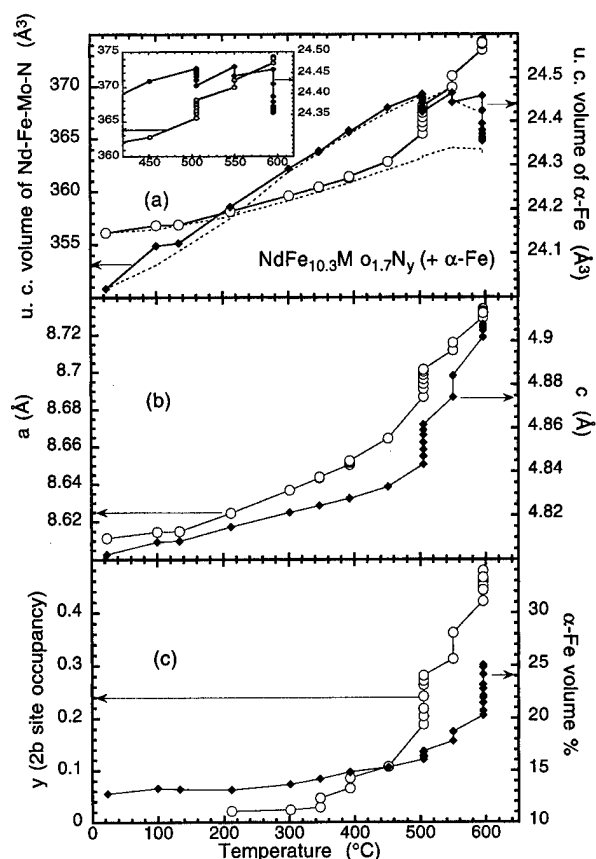

FIG. 2. The unit-cell volumes of the $\text{NdFe}_{10.3}\text{Mo}_{1.7}$ and $\alpha\text{-Fe}$ lattices (symbols) (a), the lattice parameters of the nitride phase (b), the nitrogen occupancy of the $2b$ site in $\text{NdFe}_{10.3}\text{Mo}_{1.7}\text{N}_y$, and the volume fraction of $\alpha\text{-Fe}$ (c) as a function of temperature during nitrogenation. The solid lines connect the data points each of which represents 1 h of data collection. There are 7, 2, and 9 data points at 500, 550, and 600 °C, respectively, some of which are overlapping. Typical uncertainties of the parameters are comparable to the size of the symbols. In (a) the temperature dependence of the unit-cell volumes of the $\text{NdFe}_{10.3}\text{Mo}_{1.7}$ and $\alpha\text{-Fe}$ lattices without nitrogenation is given by the dashed lines. For clarity, the high-temperature data in (a) are reproduced in the inset.

pansive pressure. Consequently, the homogeneity of the long-range atomic order is degraded and increasing microstrains are generated within crystalline domains in the temperature interval of 400–500 °C. Above 500 °C the nitrogenated domains are annealed to form larger and more relaxed crystalline grains. Concurrent with these processes the $\alpha\text{-Fe}$ particles are under compressive stress from the neighboring nitride domains and more $\alpha\text{-Fe}$ phase is nucleated in the sample.

Investigations of nitrogenation of $\text{Sm}_2\text{Fe}_{17}$ have been studied by Christodoulou and Takeshita⁵ using x-ray diffraction and thermomagnetic analysis (TMA), and by Colucci and co-workers³ using TMA and electron probe microanalysis. Electronic band calculations of model compounds within the $\text{RFe}_{12-x}\text{Mo}_x\text{N}_y$ system have been reported by several research teams.^{12,22–24} Our results agree qualitatively with the observations of these workers. Clearly, more studies, both experimental and theoretical, are needed to elucidate the atomic organization and microscopic phenomena associated with the GIM process in rare-earth transition-metal compounds.

Magnetic properties of melt-spun $\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$ ribbons have been investigated as functions of quenching rate and nitriding period. $\text{NdFe}_{10.7}\text{TiB}_{0.3}$ were prepared with substrate velocity $v_s \leq 18$ m/s and were nitrogenated at 500 °C for 15 min. The $\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$ retains the ThMn_{12} -type tetragonal structure with lattice constants $a_0 = 8.640$ Å and $c_0 = 4.811$ Å, but with an increase in the unit cell volume. The $\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$ was confirmed to have uniaxial anisotropy by x-ray diffraction. Mössbauer spectra were taken at various temperatures ranging from 13 to 855 K. The Curie and Debye temperatures are determined to be $T_c = 833$ K and $\Theta = 390$ K, respectively. Each spectrum below T_c was fitted with six subspectra of Fe sites ($8i_1$, $8i_2$, $8j_2$, $8j_1$, $8f$, and $\alpha\text{-Fe}$). The area fraction of the subspectra at 13 K are 10.2%, 8.2%, 16.5%, 17.5%, 44.3%, and 3.3%, respectively. The magnetic hyperfine fields for the Fe sites decrease in the order, $H_{\text{hf}}(8i) > H_{\text{hf}}(8j) > H_{\text{hf}}(8f)$. © 1998 American Institute of Physics. [S0021-8979(98)22811-8]

I. INTRODUCTION

Since the discovery by Yang *et al.*¹ that nitrogen absorption can enhance the Curie temperature T_c , saturation magnetization M_s , and magnetocrystalline anisotropy of RFe_{11}Ti (R=rare earth) compounds, nitrided $\text{R}(\text{Fe}, \text{M})_{12}$ (R=Sm, Nd, Gd, La, Ce, Tb, Dy, Ho, Y, or Er; M=Ti, V, Cr, Mo, Mn, W, Co, Al, or Si phases).²⁻⁵ Phases characterized by the tetragonal ThMn_{12} structure have become of interest from the perspective of permanent magnet applications. We concentrate our studies on the $\text{Nd}(\text{Fe}, \text{M})_{12}$ compound because the cost of Nd is much lower than that of Sm. The $\text{NdFe}_{11}\text{Ti}$ nitride is known to have a higher anisotropy field and Curie temperature than those of $\text{Nd}_2\text{Fe}_{14}\text{B}$.⁶

In this study, we prepared $\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$ compounds by substituting B for Ti. The crystallographic and magnetic properties of the compounds were studied using x-ray diffraction, vibrating sample magnetometry, and Mössbauer spectroscopy.

II. EXPERIMENTAL PROCEDURES

Alloys of $\text{NdFe}_{10.7}\text{TiB}_{0.3}$ were prepared by arc melting under an argon gas atmosphere. Each ingot was melt spun, again under argon, by ejecting molten alloy through an orifice in a quartz crucible onto the surface of a copper disk. The quench rate was varied by changing the surface velocity v_s of the disk, with v_s in the range 7–40 m/s. From the x-ray analysis we found that the $\text{NdFe}_{10.7}\text{TiB}_{0.3}$ starting composition yielded essentially single-phase ribbons, but only for quench rates in the $v_s \leq 18$ m/s range.

Nitriding was carried out on ground (<40 μm diam) powders of the melt-spun ribbons under a static 120 kPa pressure of N_2 gas. All samples in this work were nitrided at

773 K for 15 min. The nitrogen content in $\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$ alloys measuring by a thermopiezic analyzer is about 0.9.

A Mössbauer spectrometer of the electromechanical type⁷ was used in the constant-acceleration mode. A ^{57}Co single-line source in a rhodium matrix was used at room temperature.

III. RESULTS AND DISCUSSION

X-ray diffraction patterns show that the structure remains unchanged but that there are changes in lattice parameters as listed in Table I. The peaks in the pattern for $\text{NdFe}_{10.7}\text{TiB}_{0.3}$ can be indexed on the basis of the tetragonal ThMn_{12} -type unit cell. The $\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$ alloy exhibits a ThMn_{12} structure with unit cell constants of $a_0 = 8.640$ Å and $c_0 = 4.811$ Å, in addition to a small amount of $\alpha\text{-Fe}$. As shown in Table I, the lattice constants, a_0 and c_0 , increase markedly as nitrogen is introduced into the 1:12 structure. The relative increase in the unit-cell volume was found to be nearly constant at 1.7%. X-ray diffraction from a $\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$ powder oriented in a magnetic field perpendicular to the plane of diffraction showed a drastic increase of the intensity of the (002) peak. This result suggests that the c axis remains the easy magnetization axis.

Figure 1 shows some of the Mössbauer spectra of $\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$ measured at various absorber temperatures from 13 to 800 K. Using a least-squares computer program, six sets of six Lorentzian lines corresponding to the $8i_1$, $8i_2$, $8j_2$, $8j_1$, $8f$, and $\alpha\text{-Fe}$ sites were fitted to the Mössbauer spectra below the Curie temperature, T_c , under the following well-known restraints,⁸ which are valid when the quadrupole interaction is much weaker than the magnetic hyperfine interaction.

X-ray diffraction and the neutron diffraction data⁹ show that in $\text{Nd}(\text{Fe}, \text{M})_{12}\text{N}_\delta$ the nitrogen atoms occupy the 2b

^{a)}Electronic mail: cskim@phys.kookmin.ac.kr

TABLE I. Lattice parameters a_0 and c_0 , unit cell volume V , relative change in unit cell volume upon nitrogenation $\Delta V/V$, Curie temperature T_c , and saturation magnetization M_s of $\text{NdFe}_{10.7}\text{TiB}_{0.3}$ and $\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$.

Compound	$a_0(\text{\AA})$	$c_0(\text{\AA})$	$V(\text{\AA}^3)$	$\Delta V/V(\%)$	$T_c(\text{K})$	$M_s(\text{emu/g})$	
						$T=77\text{ K}$	$T=295\text{ K}$
$\text{NdFe}_{10.7}\text{TiB}_{0.3}$	8.587	4.788	353.05		570	124.2	113.5
$\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$	8.640	4.811	359.14	1.7	833	118.4	110.7

FIG. 1. Mössbauer spectra of $\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$ at various temperatures.

sites, whereas the iron atoms occupy the $8j$ and $8f$ sites preferentially, and M atoms reside only on the $8i$ sites. In the $\text{Nd}(\text{Fe}, \text{M})_{12}\text{N}_\delta$ structure, the distribution of M atoms may cause a distribution of Fe nearest neighbors in each Fe site, which results in quite broad outer lines in the Mössbauer spectra due to a distribution of hyperfine fields.

Using the neutron diffraction data, an acceptable fit of the Mössbauer spectra of $\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$ was performed using five sites ($8i_1$, $8i_2$, $8j_2$, $8j_1$, and $8f$). The resulting areas of the subspectra $8i_1$, $8i_2$, $8j_2$, $8j_1$, $8f$, and $\alpha\text{-Fe}$ at 13 K were 10.2, 8.2, 16.5, 17.5, 44.2, 3.3%, respectively. The $\alpha\text{-Fe}$ content of the parent compounds was less than 0.5%, so it was not included in the fits, but there was about 3% $\alpha\text{-Fe}$ in the nitride spectra. The dashed lines in Fig. 1 indicate the spectrum of $\alpha\text{-Fe}$. The Mössbauer parameters of the absorbers obtained are listed in Table II. The temperature dependence of the isomer shifts relative to $\alpha\text{-Fe}$ at room temperature, for each $8i$, $8j$, and $8f$ site increase with decreasing temperature, consistent with the second-order Doppler shift.

Figure 2 shows the temperature dependence of the magnetic hyperfine field for $\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$. The magnetic hyperfine fields for the Fe sites decrease in the order $H_{\text{hf}}(8i) > H_{\text{hf}}(8j) > H_{\text{hf}}(8f)$. The fractional change of the average magnetic hyperfine field, $[H_{\text{hf}}(T) - H_{\text{hf}}(0)]/H_{\text{hf}}(0)$, as a function of temperature is shown in Fig. 3. The average magnetic hyperfine field decreases with increasing temperature according to¹⁰ $[H_{\text{hf}}(T) - H_{\text{hf}}(0)]/H_{\text{hf}}(0) = -0.52(T/T_c)^{3/2} - 0.43(T/T_c)^{5/2}$ for $T/T_c < 0.7$. This value of

FIG. 2. Temperature dependence of magnetic hyperfine field, H_{hf} in $\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$.

$\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$ is much larger than that of the parent alloy ($B_{3/2}=0.48$ and $C_{5/2}=0.22$).⁷ Hence, it seems that spin waves having long wavelengths are excited in the nitride alloy rather than in the parent alloy.

Table I shows the VSM data before and after nitrogenation for $\text{NdFe}_{10.7}\text{TiB}_{0.3}$. The values of the Curie temperature T_c and anisotropy field H_A are estimated to be 833 K and 8 T at 295 K. It is clearly seen that nitrogenation enhances the Curie temperature of the nitrides remarkably. As Ti is replaced with B for nitrated $\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$ it is found that B is very effective for the increase Curie temperature ($T_c = 833$ K) and magnetization ($M_s = 110.7$ emu/g), which are by about 19% and 22%, respectively, larger than those of $\text{NdFe}_{10.7}\text{Ti}_{1.3}\text{N}_\delta$. In addition, considerable amounts of the α -Fe phase are formed, having higher Curie temperatures. The increase in the 1:12 Curie temperature is attributed to the increase in the Fe-Fe distance with the expansion of the unit cell volume. Above the Curie temperature, the VSM data show that the magnetic moment increases again. The

FIG. 3. Fractional change of the average magnetic hyperfine field, H_{hf} , as a function of $(T/T_c)^{3/2}$.

FIG. 4. Natural logarithm of the absorption area F vs T^2 for $\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$.

formation of α -Fe is the main reason for the increasing magnetic moment. It is worth nothing that the saturation magnetization M_s and magnetic hyperfine field H_{hf} of the nitride at 295 and at 77 K is lower than that of the parent alloy. This phenomenon was also found in $\text{NdFe}_{12-x}\text{Mo}_x\text{N}_{1-\delta}$ ² and in $\text{NdFeV}_3\text{N}_{1-\delta}$.¹¹ Although $\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$ has a lower saturation magnetization than other nitride compounds, it can very likely be used for permanent magnet in applications requiring medium or small energy products.

Figure 4 shows $\ln F$ versus T^2 for $\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$ and $\text{NdFe}_{10.7}\text{TiB}_{0.3}$, where F stands for the total resonance absorption to the recoil-free fraction f . From the temperature variation of the total Mössbauer absorption areas, we obtained the Debye temperatures of $\text{NdFe}_{10.7}\text{TiB}_{0.3}\text{N}_\delta$ and $\text{NdFe}_{10.7}\text{TiB}_{0.3}$ which are 390 ± 5 and 359 ± 5 K, respectively.

Iron powder has been nitrided in a glow discharge plasma of a mixture of nitrogen and hydrogen, in order to verify the existence of a metastable iron nitrogen solid solution, previously observed from the $\text{Sm}_2\text{Fe}_{17}\text{N}_3$ phase decomposition process. Our results show that, for short nitridation times, we obtain a mixture of Fe_4N , a small amount of $\alpha\text{-Fe}$ and an iron nitrogen solid solution the amount of which increases after heat-treatment at 610°C . This iron nitrogen solid solution is characterized by Mössbauer spectroscopy which shows a typical $\alpha\text{-Fe}$ spectrum, but with lower hyperfine field and broader linewidth. TMA measurements show that the Curie temperature is similar to that of $\alpha\text{-Fe}$. © 1998 American Institute of Physics. [S0021-8979(98)36111-3]

I. INTRODUCTION

The Fe-N binary system is of significant technological and scientific importance. Ferromagnetic iron nitride has attracted much attention because of its high magnetic flux and good corrosion and wear resistance. These properties of iron nitride are of technological interest for potential high magnetic flux density applications in severe working conditions.

Iron and nitrogen form Fe_4N , Fe_2N (Fe_3N) and Fe_8N (Fe_{16}N) phases.¹ The γ -phase austenite is stable above 590°C . The maximum solubility of nitrogen in $\alpha\text{-Fe}$ is 0.1 wt % at 590°C which decreases to ≈ 0.004 wt % when the temperature decreases to 200°C . The α -iron nitrogen solid solution has a lattice parameter and magnetic properties practically similar to those of $\alpha\text{-Fe}$. However, a recent study of the ternary $\text{Sm}_2\text{Fe}_{17}\text{N}_3$ nitride decomposition process² showed the formation of a metastable iron nitrogen solid solution with Curie temperatures lower than that for $\alpha\text{-Fe}$, ranging from 700 to 770°C . The purpose of this investigation is to verify the existence of this metastable iron nitrogen solid solution independently from the decomposition mechanism for the $\text{Sm}_2\text{Fe}_{17}$ nitride. We synthesized $\gamma'\text{-Fe}_4\text{N}$ in a glow discharge plasma and then carried out heat treatments under vacuum to promote Fe_4N decomposition.

II. EXPERIMENT

The samples were prepared by nitriding high purity (99.99%) iron powder having a particle size of about $30\text{--}50\ \mu\text{m}$. The iron powder was nitrided at 500°C in a glow discharge plasma of a mixture of N_2 and H_2 in the proportion 1:9, during periods of time ranging from 3 to 12 h. The sample temperature was monitored by a type K sheathed thermocouple. Heat treatment of the samples was carried out at 610°C under rotary pump vacuum. The samples were subsequently quenched in water. We also performed TMA measurements in order to determine both the magnetic behavior of the Fe_4N samples under decomposition and the Curie temperature of the resulting decomposition phases. The Curie temperatures were determined from the maximum

in the derivative of the susceptibility curve. The Mössbauer spectra were obtained with a conventional constant acceleration spectrometer in triangular velocity mode with a ^{57}Co source in a rhodium matrix at room temperature. The spectrometer was calibrated with a $25\ \mu\text{m}$ thick $\alpha\text{-Fe}$ foil. The density of the absorber was $2\ \text{mg Fe/cm}^2$.

III. RESULTS AND DISCUSSION

Figure 1 shows the Mössbauer spectra of as-nitrided and heat treated samples. For the as-nitrided sample the Mössbauer spectrum is basically composed of a mixture of the Fe_4N subspectrum and two $\alpha\text{-Fe}$ subspectra. The low inten-

Samples	Phases	Area (%)	H (kOe)	ΔE_Q (mm/s)	δ (mm/s)
as-nitrated	α -Fe	12.1	334	-0.01	-0.10
	ss	25.9	323	0.02	-0.07
	γ -Fe	1.5	0	0.00	-0.15
	Fe_4N	60.5	208	0.08	0.21
			210	-0.18	0.18
15 min	α -Fe	3.9	330	0.03	-0.10
			325	0.06	0.08
	γ -Fe	7.3	0	0.00	-0.15
	Fe_4N	35.0	207	0.09	0.21
			211	-0.15	0.16
	α -Fe	3.7	332	0.01	-0.09
			320	-0.02	-0.05
30 min	γ -Fe	27.9	0	0.00	-0.12
	Fe_4N	47.3	201	0.07	0.18
			203	-0.16	0.16
	α -Fe	3.7	332	0.01	-0.09
			320	-0.02	-0.05
	γ -Fe	7.3	0	0.00	-0.15
	Fe_4N	47.3	203	-0.16	0.16

sity singlets in the center of the spectrum are assigned to the austenite phase. The Fe_4N phase subspectrum is composed of three sextets (Table I). The two lower hyperfine field sextets are assigned to FeII sites (faces) A and B and the higher one is assigned to FeI sites (corner).³ The α -Fe subspectrum is composed of two sextets. The one with hyperfine field around 330 kOe is assigned to pure α -Fe and the other sextet with hyperfine field around 325 kOe and larger linewidth ($\Gamma=0.40$ mm/s) is assigned to an iron nitrogen solid solution and is ascribed to the Fe atoms whose first and second nearest octahedral interstitial sites are occupied by nitrogen atoms in the martensite phase.^{4,5} After heat treatment at 610 °C for 15 min there is a large increase of the solid solution at the expense of the Fe_4N phase. The spectrum of the sample heat

FIG. 2. TMA curve for the as nitrated sample (1st run).

FIG. 3. Sequential TMA's for the as nitrated sample.

treated at 610 °C for 30 min shows a very large increase in the austenite phase at the expense of the Fe_4N phase.

We performed a sequence of TMA measurements up to 850 °C. Figure 2 shows the TMA heating curve of the first run, for the as-nitrated sample. We observe the magnetic transition of the Fe_4N phase at around 480 °C, the signal associated with the $\gamma \leftrightarrow \alpha\text{-Fe} + \text{Fe}_4\text{N}$ transition at around 600 °C, and the magnetic transition of the α -Fe and/or the iron nitrogen solid solution at 770 °C. The following runs, up to 850 °C, reproduce the form of the heating curve of the first run. However, the Fe_4N magnetic signal decreases and the curves (Fig. 3) show a far higher value of the susceptibility. We do not observe any variation of the Curie temperature of the iron nitrogen solid solution.

IV. CONCLUSIONS

Iron nitrogen solid solution can be formed in the iron samples nitrated in a glow discharge of mixture of a nitrogen and hydrogen. The Mössbauer spectrum of the iron nitrogen solid solution is typical of α -Fe, but with a lower hyperfine field around 325 kOe and a larger linewidth of $\Gamma=0.40$ mm/s. The Curie temperature observed is similar to that for α -Fe. This contrasts with the case of the metastable iron nitrogen solid solution resulting from the $\text{Sm}_2\text{Fe}_{17}$ nitride decomposition process which showed a different Curie temperature.

Macroscopic Quantum Tunneling and Spin Dynamics

Bruce Harmon, Chairman

Experimental evidence of macroscopic resonant tunneling of magnetization in antiferromagnetic ferritin

Macroscopic resonant quantum tunneling of magnetization has been observed in antiferromagnetic ferritin particles. The dependence of magnetic viscosity on the applied magnetic field has been systematically investigated in the temperature range 1.8–10 K. The zero maximum in field dependence of viscosity and the maximum in the field dependent blocking temperature are interpreted to be due to the resonant spin tunneling between matching spin levels. © 1998 American Institute of Physics. [S0021-8979(98)53311-7]

Since the discovery of the resonant quantum tunneling in high-spin molecules,^{1–4} we have been working in order to observe the same phenomena in mesoscopic particles with much higher spin values. The main problem when using mesoscopic particles is that they are not identical. In a typical sample of magnetic nanoparticles there is a distribution of spin values and a random orientation of the easy axis. These facts make it difficult to observe fine behaviors like the resonant quantum tunneling of magnetization. However, as we have recently published,⁵ it is possible to detect this effect in ferritin molecules because: (a) the magnetic core of these molecules is antiferromagnetic therefore having higher crossover temperature between the classical and quantum regime than ferromagnetic particles, (b) the net spin is small and the anisotropy barrier height is large making experimentally possible the observance of the discrete orientation of the magnetic moment, and (c) the molecules are independent between them, which very much simplifies the explanation.

The quantum dynamics of magnetization in ferritin have received much attention since Awschalom and co-workers reported a resonance in the absorption spectrum of ferritin in the range of milliKelvin, which they attributed to the macroscopic quantum coherence.⁶ This hypothesis establishes an important paradox:⁷ while the Kelvin range experiments indicate that the magnetic moments of the particles are frozen below a few Kelvin (the blocking temperature of ferritin is about 13 K),⁸ the resonance experiments in the milliKelvin range were interpreted as the quantum tunneling of spin with a rate of 10^6 – 10^7 s^{−1}. The explanation to this paradox could be the following: resonant quantum tunneling only occurs when the levels of the opposite orientation of the spin coincide at both wells. If this is true, we should be able to observe an increase of the relaxation rate around zero magnetic field. We report that this is what exactly occurs in ferritin.

In our experiments we have used a dilute sample of natural ferritin with about 10^{14} molecules. The ferritin has a spherical cavity of 8 nm which contains mineral ferrihydrite with phosphate. Its core is equivalent to a magnetic particle with a diameter between 3 and 7.5 nm. The ferritin core contains about 4500 Fe³⁺ ions. However, the spin of the particle is small (around 100). This is due to the antiferromagnetic magnetic order between the two sublattices of the Fe³⁺ ions. Only about 15 noncompensated surface spins contribute to the magnetic moment of the particle, which coincides with the theoretical estimation of $(4500)^{1/3} \approx 16$. This noncompensated spin locks in one of the two directions along the anisotropy axis of the particle. The interactions between particles can be neglected as both the ac and dc magnetic susceptibility experiments on samples with different dilution degree indicate. Above 13 K the particles are superparamagnetic,⁸ as it has been proved by ac and dc susceptibility measurements, that is, their magnetic moments frequently jump between the two opposite orientations over the anisotropy barrier. Below 13 K the particles are essentially frozen and the transition from s to $-s$ can occur only due to quantum tunneling: in the absence of the magnetic field and in the limit of weak dissipation, sublattices should interchange in a coherent manner.⁹

Gider¹⁰ and Friedman¹¹ brought to light a nonmonotonic behavior of the field dependence to the blocking temperature, T_B . The variation of T_B with the applied field deduced from our experiments of the zero field cooled (ZFC) magnetization are shown in Fig. 1. We can observe a nonmonotonic dependence of the blocking temperature as a function of magnetic field. Contrary to what is expected in this kind of system, the blocking temperature increases when the magnetic field increases. This anomalous behavior is observed up to 2.5 kOe, where it reaches its maximum and then decreases at higher fields following the expected behavior.

The measurements of the ZFC magnetization have been

^{a)}Electronic mail: edb@ffn.ub.es

FIG. 1. Zero field cooled magnetization curves obtained by cooling the sample in zero field and then heating it at different applied field. The inset shows the field dependence of the blocking temperature.

obtained by cooling the sample down to 2 K without applied field. Then a magnetic field is applied. Afterwards, the magnetization is measured while the temperature increases. The process is repeated at different magnetic fields. At low temperature, the magnetization of the system is small because the particles are frozen and they cannot jump over the anisotropy barrier and solely the smallest particles can arrange its magnetic moment along the applied field. As the temperature increases, every time bigger particles rotate their magnetic moments contribute to increase the magnetization. The blocking temperature, T_B , is defined as the temperature at which the majority of the particles become unfrozen, at the time scale of the experiment. T_B is therefore proportional to the anisotropy energy barrier $U = KV$, where K is the anisotropy energy constant and V is the volume of the particle. At temperatures over T_B , $M(T)$ follows the Curie law of the superparamagnetism.

Another way to verify the acceleration of the magnetic relaxation towards the equilibrium state at zero field is the magnetic hysteresis measurement. The field derivative of the magnetic hysteresis loops explains how fast the system reaches the equilibrium. The peaks observed in both the hysteresis loops of the Mn_{12} -Ac molecules were the key elements in the discovery of the resonant spin tunneling. In the hysteresis loops of ferritin we observe⁵ a clear peak at zero magnetic field (Fig. 2). The peaks at non-zero-magnetic field values are not detectable because of the impossibility to orient the ferritin molecules with their easy axis parallel to the applied magnetic field.

Finally we confirmed the acceleration of the magnetic relaxation at $H=0$ by measuring directly the relaxation rate as a function of the applied magnetic field.⁵ The method is the following: the sample is cooled from 50 K down to the measurement temperature. Then a magnetic field is applied and the magnetization is measured during the relaxation to the equilibrium state. The relaxation behavior is, with high accuracy, logarithmic in time during four decades (Fig. 3). This is a typical behavior in a system with broad distribution of energy barriers. The control parameter of the relaxation is the magnetic viscosity defined as

FIG. 2. Field derivative of the magnetization at a constant sweep rate. Inset shows hysteresis loops from which dM/dT has been obtained (Ref. 5).

$$S = \frac{1}{M_{eq}(H,T)} \frac{dM(H,T,t)}{d \ln(t)}, \quad (1)$$

where $M_{eq}(H,T)$ is the equilibrium magnetization of the system at fixed temperature and field. The latter was deduced from the field cooled magnetization measurements.

The magnetic viscosity as a function of the applied magnetic field at different temperatures is shown in Fig. 4.⁵ At 2.4 and 3 K the viscosity increases with the magnetic field. In the range from 4.2 to 8 K the viscosity first decreases when the applied magnetic field increases, reaches its minimum at one value of the applied field which depends on the temperature, and then increases at higher fields. Over 8 K the viscosity always decreases monotonically.

This unusual behavior of the magnetic relaxation in ferritin can be explained if one takes into account quantization of spin levels of the particle. The lower spin levels should be separated by the energy of the antiferromagnetic resonance, $\Delta E = (2\epsilon_{an}\epsilon_{ex})^{1/2}$, where $\epsilon_{an} = g\beta H_{an}$ is the anisotropy energy and $\epsilon_{ex} = JS$, where J is the exchange constant and S is the sublattice spin. This energy is much bigger than the one

FIG. 3. Time dependence of the magnetization at different applied fields at 6.5 K. The numbers near the data are the values of the applied magnetic field in Oe.

FIG. 4. Magnetic viscosity as a function of the magnetic field at different temperatures (Ref. 5).

corresponding to ferromagnetic particle with the same size. In ferritin, this energy is about 10 K which is comparable to the separation of the lower levels in Mn_{12} molecules.

The resonant quantum tunneling between the matching spin levels occurs when $2g\beta Hs = n\Delta E$, where $n=0,1,2,\dots$. All the corresponding values of the magnetic field are separated by

$$\Delta H = \frac{H_{\text{an}}}{2s} \left(\frac{2\epsilon_{\text{ex}}}{\epsilon_{\text{an}}} \right)^2. \quad (2)$$

For a ferromagnetic particle, the separation between the low levels can be estimated around 0.1 Oe. This value is smaller than the splitting of the levels and the resonance will not be observable. However, this value for the same particle of spin S with antiferromagnetic order is a factor $(S/s) (\epsilon_{\text{ex}}/\epsilon_{\text{an}})^{1/2}$ bigger, which in ferritin is a factor 10^4 . Consequently, the field spacing between resonances in ferritin must be of order of kOe, that is, comparable to that in Mn_{12} . However, due to the different orientation and magnitude of the noncompensated spin, contrary to the case of a Mn_{12} crystal, only the $H=0$ resonance occurs simultaneously in all ferritin particles. To see high order resonances one must have a sample with oriented ferritin particles having a single s value.

As in $\text{Mn}_{12}\text{-Ac}$, in ferritin the tunneling in our temperature range must be thermally assisted, this is, it occurs from excited spin states as well as from the ground state. The spin states are characterized by the projection of s on the anisotropy axis, $s_z|m\rangle = m|m\rangle$. At $H=0$ the states corresponding to m and $-m$ are degenerated and the resonant tunneling between these states takes place. At low temperature (below

3 K) only the lowest levels $m = \pm s$ are occupied. The tunneling splitting of these levels is given by

$$\Delta_S \propto T_c \exp \left[-S \left(\frac{\epsilon_{\text{an}}}{\epsilon_{\text{ex}}} \right)^{1/2} \right], \quad (3)$$

where T_c is the crossover temperature, which in ferritin is about 3.2 K. This tunneling splitting determines the width of the resonance with the magnetic field. Since tunneling is weak this width is extremely small. According to Ref. 6 where measurements were performed in the mK range, the width of this resonance is about 10^{-4} Oe. This should explain why we do not see the $H=0$ peak in the viscosity at low temperature. As the temperature increases above 3 K, higher m levels become thermally populated and tunneling between them dominates the relaxation. The width of these levels must be large due to their finite lifetime with respect to the decay down to the ground state levels $m = \pm s$. Consequently, the width of the resonance on the magnetic field becomes large enough to observe the $H=0$ maximum in the viscosity. As the temperature continues to increase towards the blocking temperature, the system enters the superparamagnetic regime dominated by thermal overbarrier transitions. In this regime the viscosity monotonically decreases with the field, reflecting the progressive disappearance of the metastability.

In conclusion, we have presented data on the magnetic relaxation in ferritin which show strong departure from the conventional behavior. A plausible explanation to all data is given within the model of thermally assisted resonant tunneling between spin levels.

The response of the magnetization to a time-dependent applied magnetic field in single-spin models for uniaxial magnets is studied. We present staircase magnetization curves obtained from the numerically exact solution of the time-dependent Schrödinger equation. Steps are shown to correspond to field-tuned quantum tunneling between different pairs of nearly degenerate energy levels. We investigate the role played by different terms that allow for tunneling processes: transverse fields and second-order and fourth-order transverse anisotropies. Magnetization curves for nonsaturated initial states and for excited initial states showing steps when the field decreases in absolute value are also presented. These results are discussed in relation to recent experiments on high-spin compounds. © 1998 American Institute of Physics. [S0021-8979(98)16111-X]

Magnetic molecules containing high-spin clusters¹ such as Mn_{12} or Fe_8 provide physical systems by which to study quantum tunneling of the magnetization (QTM).^{2,3} Recent experiments on these systems^{4,5} have reported the appearance of steps in the hysteresis loops at low temperature which have been attributed to thermally assisted resonant tunneling between quantum states. This interpretation is based on a single-spin $S=10$ model with strong uniaxial anisotropy ($\mathcal{H} = -DS_z^2 - g\mu_B \mathbf{S}\mathbf{H}$, where D is the uniaxial anisotropy energy) for which energy levels ($|Sm\rangle$ for $\mathbf{H} \parallel \hat{z}$, where $S_z|Sm\rangle = m|Sm\rangle$) cross at fields $g\mu_B H_n = nD$. At these fields, the relaxation time of the magnetization shows minima. For QTM to occur, this model has to be extended to include symmetry breaking terms such as those originating from dipolar interaction, interaction with nuclear spins or phonons, etc.⁵⁻⁷ The detailed mechanism by means of which QTM occurs in hysteresis experiments on uniaxial magnets is investigated in this article. Previously, magnetization tunneling in mesoscopic systems has been semiclassically studied by several authors⁸⁻¹⁰ and, more recently, quantum dynamical calculations for several models of nanomagnets such as the Heisenberg model¹¹ and the single-spin quantum model¹² have shown the occurrence of resonant coherent QTM at zero temperature. The staircase structure in the magnetization curves for a time-dependent field has been recently shown¹³ to be well described by successive Landau-Zener (LZ) transitions.^{14,15} In addition, recent theoretical works have also studied the problem of spin tunneling in a swept magnetic field.^{16,17}

The most general Hamiltonian for a single quantum spin including a transverse field (which might have a hyperfine or dipolar origin), second-order and fourth-order transverse anisotropies, and a time-dependent applied magnetic field is

$$\mathcal{H} = -K_x S_x^2 - K_y S_y^2 - K_z S_z^2 - C_x S_x^4 - C_y S_y^4 - C_z S_z^4 - \Gamma S_x - \mathbf{H}(t)\mathbf{S}, \quad (1)$$

where K_z , K_x and K_y are the anisotropy constants along the easy, medium, and hard axes, respectively, $\mathbf{S} = (S_x, S_y, S_z)$ is the vector representing the magnetization, C_x , C_y , and C_z are the fourth-order anisotropy constants, Γ is the transverse field, and $\mathbf{H}(t) = H(t)(\sin \theta, 0, \cos \theta)$ denotes the applied field.

The time evolution of the magnetization at $T=0$ is obtained from the exact numerical solution of the time-dependent Schrödinger equation (TDSE), $i\hbar \partial |\Psi(t)\rangle / \partial t = \mathcal{H} |\Psi(t)\rangle$, where $|\Psi(t)\rangle$ denotes the wave function of the spin system at time t . We study the following situation: First we set the applied magnetic field to its minimum value $H(t=0) = -H_0$ and put the system in the corresponding ground state, i.e., $|\Psi(0)\rangle = |\Phi_0(0)\rangle$ where $\mathcal{H}(-H_0)|\Phi_0(0)\rangle = E_0(-H_0)|\Phi_0(0)\rangle$. The time evolution of the wave function is then calculated by means of $|\Psi(t+\tau)\rangle = \exp(-i\tau\mathcal{H})|\Psi(t)\rangle$, where τ is the time step used to integrate the TDSE. During the integration of the TDSE, the applied field changes from $-H_0$ to H_0 with a given speed, which is defined by the field step ΔH between two consecutive field values and the amount of time τ_H the system feels each constant field. The temporal evolution of the α th ($\alpha = x, y, z$) component of the spin can be calculated from $\langle S_\alpha(t) \rangle = \langle \Psi(t) | S_\alpha | \Psi(t) \rangle$. For each constant field value we compute the expectation value of S_α averaged over time $\bar{S}_\alpha = 1/\tau_H \int_0^{\tau_H} dt \langle S_\alpha(t) \rangle$. In the following we will refer to $M = \bar{S}_z/S$ as the magnetization. The energy of the system is given by $E[H(t)] = \langle \Psi(t) | \mathcal{H} | \Psi(t) \rangle$.

In order to understand the origin of the steps in the magnetization curves, we first consider the simplest case of (1), namely, a single spin 1/2 system described by the Hamiltonian $\mathcal{H} = -\Gamma \sigma_x - H(t)\sigma_z$, where σ_x and σ_z are the Pauli-spin matrices, and we study the response of the magnetization to the time-dependent applied field $H(t)$. Γ sets the scale of the splitting at $H=0$ between the two energy levels (see inset of Fig. 1). Figure 1 presents the magnetization curves for several field sweep rates for the ground state as the initial state, showing steps of different sizes at $H=0$.

^{a)}Electronic mail: danielgp@fsp.csic.es

FIG. 1. M vs H for model (1) with $S=1/2$, $K_z=1.0$, and $\Gamma=0.02$ for several field sweep rates $\Delta H/\tau_H$: $\Delta H=0.001$ and (a) $\tau_H=0.1$, (b) $\tau_H=1$, (c) $\tau_H=2$, and (d) $\tau_H=5$. Initial state: Φ_0 . The inset shows the levels crossing and the system energy for cases (a)–(d).

According to the adiabatic theorem, a slowly changing external perturbation will keep the system in the eigenstate it started from (Φ_0) unless this eigenstate comes closer to another eigenstate (Φ_1). Then the adiabatic approximation might break down, allowing the system to escape from Φ_0 and tunnel to Φ_1 via the Landau–Zener tunneling mechanism.¹⁴ The probability of staying in the same eigenstate Φ_0 (which has opposite magnetization after the crossing) when the field is swept is given by $p=1-\exp[-\pi\Delta E^2/(2\Delta H/\tau_H)]$, which depends on the energy splitting and the field sweep rate $\Delta H/\tau_H$. The final state is then a linear combination of both eigenstates with weights p and $1-p$ and the size of the step at $H=0$ is proportional to p , i.e., $\Delta M=pM_0^{\text{final}}+(1-p)M_1^{\text{final}}-M_0^{\text{initial}}$, where the superscripts initial and final refer to before and after the crossing. Curve (d) is the closest to adiabatic behavior ($p\approx 1$, large step); curve (a) corresponds to a fast sweep and the scattering is almost complete ($p\approx 0$, small step). The appearance of steps in the magnetization curves is a general feature for many models of uniaxial magnets and follows naturally from the occurrence of field-tuned tunneling transitions between nearly degenerate eigenstates of the Hamiltonian. The size of the step depends on the energy-level splitting of the participating levels, the weight of the corresponding eigenstates in the current state of the system, the field sweep speed, and the value of the magnetization itself.

In Fig. 2 we present magnetization curves for the Hamiltonian most commonly assumed^{4,5} in the attempt to explain recent experimental data ($\mathcal{H}=-K_z S_z^2-\mathbf{H}(t)\mathbf{S}$, with $\mathbf{H}\parallel\hat{z}$ and $S=10$), supplemented by terms that break the rotational symmetry about the z axis, i.e., those in model (1). These terms allow for the occurrence of field-tuned QTM and the corresponding steps in the magnetization. All these cases have in common that, for some specific fields H_n , pairs of energy levels become almost degenerate. If $\Phi_0(-H_0)$ is the initial state, the levels involved in the crossing at H_n are E_n and E_{n+1} .

Curves (a), (b), and (c) correspond to the case including

FIG. 2. M vs H for model (1) with $S=10$, $K_z=1$, and $\theta=0^\circ$ supplemented by a transverse field term for Γ equal to (a) 0.5, (b) 2, and (c) 6.5; second-order anisotropy terms with $K_x=0.6$ and K_y equal to (d) 0.5, (e) 0.4, and (f) 0.1; and fourth-order anisotropy terms with $C=C_x=C_y=C_z$ equal to (g) 0.0005, (h) 0.0025, and (i) 0.01. Field sweep parameters for (a), (b), (c): $\Delta H=3\times 10^{-5}$, $\tau_H=1200$; for (d), (e), (f): $\Delta H=2\times 10^{-5}$, $\tau_H=800$; for (g), (h), (i): $\Delta H=3\times 10^{-5}$, and $\tau_H=900$.

a transverse field. Γ allows all transitions $\Delta m=\pm 1$. At resonance $H_n=nK_z=n$, and the values of n for which steps appear depend on Γ . Thus, for (a) $\Gamma=0.5K_z=0.5$ we find $n=12,13,14$; for (b) $\Gamma=2$, $n=8,9$; and for (c) $\Gamma=6.5$, $n=1,2,3$.

Curves (d), (e), and (f) show that the presence of second-order transverse anisotropy terms can also induce QTM. They correspond to $K_z=1$, $K_x=0.6$, and several values of K_y . For $K_y=K_x$, the energy and S_z commute and no tunneling occurs. These transverse anisotropy terms change the spacing between resonant fields although they remain regularly spaced as in case the case of a transverse field Γ . These terms allow transitions that obey the selection rule $\Delta m=\pm 2$. For (d) $K_y=0.5$, $n=8,10$; for (e) $K_y=0.4$, $n=4,6,8$; and for (f) $K_y=0.1$, $n=2,4$.

Fourth-order anisotropy terms [curves (g), (h), and (i)] allow the occurrence of field-tuned tunneling between levels satisfying $\Delta m=\pm 4$. In this case, the fields at which pairs of energy levels cross are not equally spaced. Results are shown for different values of $C_x=C_y=C_z=C$. For (g) $C=0.0005K_z=0.0005$, $n=8,12$; for (h) $C=0.0025$, $n=4,8,12$; and for (i) $C=0.01$, $n=0,4,8$.

None of the curves in Fig. 2 presents steps when $|\mathbf{H}|$ decreases. This can be easily understood since the system starts from the ground state Φ_0 and the energy level scheme as a function of the field is such that E_0 only crosses another level at zero field. Another feature of these curves is that the magnetization does not reach the saturation value (unless the system stays in the ground state when crossing $H=0$ in which case there is one big step from $M=-1$ to $M=1$) even for $H\rightarrow\infty$. The explanation comes from the fact that the system can only gain or lose energy through the time-dependent field but not through interaction with the environment.

The field sweep rate ($\Delta H/\tau_H$) is a crucial parameter in this problem. As was shown for the simple case of a single

FIG. 3. M vs H for model (1) with $S=10$, $K_x=0.6$, $K_y=0.1$, $K_z=1.0$, $C=\Gamma=0$, and $\theta=0^\circ$. Curves (a) and (a'): The field goes (a) from $-H_0$ to H_0 and (a') from H_0 to $-H_0$ for $H_0=10.0$, starting from the initial states: $\Psi_{(a)}^{(a')}(0)=c_0\Phi_0(\mp H_0)+c_1\Phi_1(\mp H_0)+c_2\Phi_2(\mp H_0)$, respectively, where $c_0=0.7$, $c_1=0.22$, and $c_2=0.08$. Field sweep parameters: $\Delta H=0.0025$, $\tau_H=10^5$. Curve (b): The initial state is $\Phi_0(-H_0)$ and the field goes from $-H_0$ to H_0 and then, before reaching saturation, back to $-H_0$ for $H_0=10.0$. At $H=H_0$, where the field is reversed, $\Psi(H_0)=\sum_n c_{2n}\Phi_{2n}(H_0)$, where $c_0=0.168$, $c_2=0.653$, $c_4=0.038$, $c_6=0.111$, $c_8=0.027$, and $c_{10}=0.002$.

spin $1/2$, the probability of QTM depends on it. In general, the lower the sweep rate, the larger the size of the step. However, also relevant is the smoothness of the field swept: If ΔH is too large, the size of the steps depends in a non-trivial way on ΔH , τ_H , and ΔE , and LZ theory does not apply.

In Fig. 3 we consider the case of an initial state which is not the ground state but a linear combination of several eigenstates. Unlike the ground state, the excited levels can become nearly degenerate with other levels for $H \neq 0$, and therefore there is a nonzero probability of finding steps when $|H|$ decreases, as illustrated by curves (a) and (a'). Moreover, if the field is reversed after one sweep from $-H_0$ to H_0 [curve (b)], the system restarts from a linear combination of several eigenstates (corresponding to a nonsaturated state in an experiment) and the situation is similar to that of curves (a) and (a'). As shown by curve (b), there is some probability of finding steps when $|H|$ decreases and of getting both negative and positive steps. The same reasoning applies to QTM from thermally populated excited levels. Although the tunneling probability increases with the excitation level, and smaller off-diagonal terms are required to induce field-tuned QTM, the fact that the tunneling processes involve excited levels implies that some probability of finding steps when $|H|$ decreases exists, at variance with the experimental results. Moreover, preliminary experimental results in which the field is reversed before saturation is reached show that steps can appear when $|H|$ decreases,¹⁸ in qualitative agreement with our findings.

We have shown that $T=0$ field-tuned QTM leads to staircase magnetization curves. The following might be relevant when comparing to experiments^{4,5} on Mn_{12} : A trans-

verse field Γ allows $\Delta m = \pm 1$ transitions and yields equally spaced steps, in agreement with experiments. However, the theoretical magnetization curves [with Γ as the only off-diagonal term and $\Phi_0(-H_0)$ as the initial state] look similar to the experimental ones (steps at the first energy level crossings $g\mu_B H_n = nD$, n small) for much larger values ($\Gamma \sim 1-5D \equiv 0.44-2.2T$) than those estimated for dipolar ($\sim 0.01T$) or hyperfine ($\sim 0.05T$) interactions.¹⁹ Second-order transverse anisotropy terms are often discarded due to Mn_{12} tetragonal symmetry, although local symmetries could affect the structure of the spectrum. These terms are relevant for other systems such as Fe_8 .²⁰ Fourth-order anisotropy terms cannot account for all the steps observed and they lead to nonequally spaced steps. They can be responsible for small deviations from $\Delta m = \pm 1$ transitions and equally spaced steps. However, the single-spin model proposed for the Mn_{12} molecule may be too simple to mimic the actual energy spectrum: The single-spin $S=10$ system is described by 21 eigenstates whereas a proper description of the magnetic state of the Mn_{12} molecule requires 10^8 states. A better understanding of the situation when the field is not swept smoothly enough and the Landau-Zener picture does not apply is also needed, especially since this appears to be the experimental case. Finally, further experimental work investigating the possibility of obtaining steps for decreasing $|H|$ and observing negative (opposite to the field sweep) steps may clarify the effect of thermal activation, which in principle allows the appearance of these steps.

Resonant magnetic quantum tunneling through thermally activated states

J. F. Fernández, J. Bartolomé, and F. Luis^{a)}

Instituto de Ciencia de Materiales de Aragón, C.S.I.C.-Universidad de Zaragoza, 50009- Zaragoza, Spain

A theory of the magnetic relaxation of a large spin ($S=10$) having a large uniaxial magnetocrystalline anisotropy is outlined. The theory explains magnetic relaxation observed in Mn_{12} acetate. The *joint* action of local fields and a fourth order distortion of the magnetocrystalline anisotropy is necessary to account for the tunneling that is observed, between the $m=-4$ and $m=4$ unperturbed states. Even in resonance, tunneling takes place mainly incoherently in Mn_{12} acetate. It proceeds through the lowest energy state doublet which is not blocked by longitudinal local fields. The relaxation rate Γ has been calculated using a master equation. The model gives magnetization hysteresis loops and ac magnetic susceptibility curves which are in quantitative agreement with experimental results. For temperatures below 0.5 K approximately, nonresonant tunneling from the ground state becomes the dominant relaxation mechanism. © 1998 American Institute of Physics. [S0021-8979(98)18611-5]

We present a theory of quantum tunneling through thermally activated states of a large quantum spin. Ours differs from other theories which have been presented recently^{1,2} in two respects: (1) our master equation involves eigenstates of the exact Hamiltonian for the spin, whereas eigenstates of S_z are used in Refs. 1 and 2; (2) the spin Hamiltonian of Ref. 1 contains only off diagonal terms which are linear in S_x (or S_y), arising from random internal fields, whereas we show below that only the joint action of linear and quartic (result of the anisotropy) spin terms can give an account of the tunneling observed experimentally in Mn_{12} acetate.² The main purpose of this contribution is to give numerical results, that follow from our theory, which can be compared to experiments in Mn_{12} acetate.³

I. SPIN HAMILTONIAN: RESONANCE CONDITION

Our model is based on the following spin Hamiltonian:⁴

$$\mathcal{H} = -DS_z^2 + \mathcal{H}'_1 + \mathcal{H}'_2, \quad (1a)$$

where

$$\mathcal{H}'_1 = -A_4 S_z^4 - g\mu_B H_z S_z \quad (1b)$$

and

$$\mathcal{H}'_2 = C(S_+^4 + S_-^4) - g\mu_B H_x S_x. \quad (1c)$$

The first term in \mathcal{H} favors the spin alignment along the z direction (c crystallographic axis of Mn_{12} acetate). The two local energy minima are separated by an energy barrier $U = DS^2 + A_4 S^4$ (≈ 70 K in Mn_{12} acetate⁵). \mathcal{H}'_1 and \mathcal{H}'_2 are stationary perturbations. They include higher order anisotropy terms and the interaction with the local magnetic field \mathbf{H} . In Mn_{12} acetate, this local field is a superposition of an external applied field \mathbf{H}^0 and an internal field \mathbf{H}_d , where the effect of dipolar and hyperfine interactions are included.⁴

Unperturbed states $|m\rangle$ and $|-m\rangle$ are degenerate. The diagonal perturbation \mathcal{H}'_1 upsets this resonance condition. New resonance conditions for $|m\rangle$ and $|-m-n\rangle$ are

achieved if $H_z = H_{nm}$, where $H_{nm} = n(1 + \alpha_{nm})D/g\mu_B$, $\alpha_{nm} = (A_4/D)[m^2 + (m+n)^2]$, and $n=0,1,2,\dots$

In resonance, the off diagonal terms induce tunneling between these degenerate unperturbed states and lift the degeneracy by $\Delta\hat{E}_{l,l+1}$. Index l labels eigenstates $|\Psi_l\rangle$ of \mathcal{H} in increasing order of energy. Consider large deviations from the resonance condition above. More specifically, if $g\mu_B(2m+n)|H_{nm} - H_z| \gg \Delta\hat{E}_{l,l+1}$ the eigenfunctions of \mathcal{H} become localized on either side of the energy barrier, and quantum tunneling becomes blocked. In resonance only random dipolar fields contribute to $H_{nm} - H_z$. Then, the above inequality is *not* fulfilled for upper energy levels, through which tunneling proceeds freely.

Both terms in Eq. (1c) are necessary in order to explain the magnetic relaxation observed experimentally in Mn_{12} acetate.⁶ For $H_z = nH_1$, and n odd, the fourth order spin term alone would give $\Delta\hat{E} = 0$ for all energy levels, whereas quantum tunneling is observed for such field values. Therefore, it is necessary to consider the interaction with the internal field. However, this perturbation, by itself, is not sufficient. For Mn_{12} acetate, $H_{dx} \approx (\sqrt{2})H_{dz} \approx 6 \times 10^{-2} H_1$.³ Using this value, it follows that $\Delta\hat{E}_{l,l+1} \ll 2g\mu_B m H_{dz}$ for states $m=4, -4$ ($l=13$). This would be in disagreement with tunneling experiments in Mn_{12} acetate.⁷ We find that joint action of both interactions leads to good agreement with experiments^{7,8} using $D=0.60$ K, $A_4/D=1.7 \times 10^{-3}$, $C/D=5.1 \times 10^{-5}$, and $H_{dx}=6.4 \times 10^{-2} H_1$. These parameters are, within given errors, the ones obtained from high field electron paramagnetic resonance (EPR) experiments.⁵

II. QUANTUM TUNNELING THROUGH THERMALLY ACTIVATED STATES

In Mn_{12} acetate above 2 K, tunneling occurs through excited states.^{3,7} Consider a spin interacting with a thermal bath. Assume an initial state $|\Psi_i\rangle$ with low energy E_i , which is localized on the left-hand side of the energy barrier and that no field is applied. Phonon induced transitions involving a large change in the magnetic number m have a negligible

^{a)}Electronic mail: fluis@posta.unizar.es

FIG. 1. Calculated (continuous line) and experimental (points) relaxation rate at $T=5$ K as a function of the longitudinal applied field. H_1 is, in every case, the smallest nonzero field where Γ peaks.

probability. Therefore, absorption of a phonon brings the system to a higher energy state, localized on the same side of the barrier. The final state is a coherent superposition of two energy eigenstates $|\Psi_l\rangle$ and $|\Psi_{l+1}\rangle$, that differ in energy by $\Delta E_{l,l+1}$, if $g\mu_B(2m+n)|H_z - H_{nm}| > \Delta E_{l,l+1}$. Energy conservation does not allow such *coherent* superposition to last for times much longer than $\hbar/\Delta E_{l,l+1}$. On the other hand, $g\mu_B H_{dz} \gg \hbar/\tau_0$, where $\tau_0 \approx 10^{-7}$ s is a typical lifetime of an excited state, holds for Mn_{12} . It follows then that $\tau_0 \gg \hbar/\Delta E_{l,l+1}$. Consequently, the system is in an *incoherent* superposition of energy eigenstates most of the time before it decays into states localized on the other side of the energy barrier. There is a nonvanishing probability to decay on the opposite side of the energy barrier, because these excited energy eigenfunctions extend over both positive and negative m values. When the local field deviates from its resonant value, states become more localized, and, consequently, the total relaxation rate decreases. This scheme explains qualitatively the resonance observed experimentally at every crossing field. A more quantitative account follows.

Since incoherence prevails, the time evolution of $\langle S_z \rangle$, can be calculated with Pauli's master equation. Transition

FIG. 2. Relaxation rate (in logarithmic scale) as a function of the inverse temperature at several values of the transverse local field (in units of $D/g\mu_B$) and fixed $H_z = 10^{-3} D/g\mu_B$.

FIG. 3. Crossover temperature (see the text) for $H_z = 10^{-3} D/g\mu_B$ as a function of the transverse local field.

probabilities between numerically exact energy eigenstates l and l' have been calculated using Fermi's Golden Rule, as in Ref. 9, which gives

$$W_{l' \leftarrow l} = q |E_l - E_{l'}|^3 |\langle E_{l'} | B(S) | E_l \rangle|^2 A_{l,l'}, \quad (2)$$

where $A_{l,l'} = n_{l,l'}$ and $A_{l,l'} = 1 + n_{l,l'}$ for upward and downward transitions, respectively. Here, $n_{l,l'} = 1/[\exp(\Delta E_{l,l'}/k_B T) - 1]$ is the average number of phonons of energy $\Delta E_{l,l'}$. We have chosen the simplest operator $V = [S_x, S_z]_+ + [S_y, S_z]_+$ which is Hermitian and time reversal invariant. The term q is a parameter which measures the strength of the spin-phonon interaction. We chose its magnitude to give best agreement between the calculated ac susceptibility and experimental data obtained at $T=5$ K. Results from our calculations are compared to experimental results in the following section.

III. RESULTS

Numerical calculations show⁶ that $\langle S_z \rangle_l$ relaxes exponentially to equilibrium, except for a very short initial time interval (of the order of τ_0). The relaxation rate Γ equals the absolute value of the largest nonzero eigenvalue of the transition matrix W . Γ for $T=5$ K is plotted as a function of the applied field in Fig. 1. As expected (see Sec. II) maxima of Γ appear at crossing field values, in good agreement with experiments.⁸

When $H_x = H_{dx}$, that is, if no transverse field is applied, Γ follows Arrhenius law $\Gamma = \Gamma_0 \exp(U_{ef}/k_B T)$, at least in the temperature range $0.1 < D/k_B T < 0.35$ for all values of the longitudinal field. This means that there is only one relaxation channel in this temperature range.

As the magnitude of the transverse field increases, lower lying tunneling state pairs may become unblocked. Consequently, U_{ef} decreases, as inferred from the slope of the Γ vs $1/T$ curves in Fig. 2. Below a crossover temperature T_Q , thermal population of the excited states becomes so small that the spin reversal can only take place by nonresonant tunneling from the ground state.⁴ Thus, Γ is temperature independent below T_Q (see Fig. 2). As H_x increases, the probability for this tunneling mechanism increases. Consequently, T_Q becomes larger (see Fig. 3). If $H_x > 12 H_1$, the

FIG. 4. Magnetization, in units of $g\mu_B$, as a function of the longitudinal applied field. Points represent experimental data at different temperatures; \circ , 1.77 K; \bullet , 2.1 K; \square , 2.64 K. Continuous lines stand for the results of our numerical calculations.

ground state is not blocked by H_{dz} and coherent tunneling can proceed, unassisted, through the ground state doublet.

Knowledge of Γ enables us to calculate magnetization hysteresis loops. Internal fields vary almost randomly between different molecules. In order to compare the results of our calculations to experiments, all physical magnitudes have been broadened using a Lorentzian distribution of local fields, with standard deviation $\sigma = 4 \times 10^{-2} H_1$. Figure 4 shows hysteresis loops calculated at three different temperatures, which are in reasonable agreement with the experiments.³ The field is changed in steps of $10^{-2} H_1$ and the best fit is obtained if it is kept constant for 15 s.

Our calculations show that, to a good approximation, only the smallest eigenvalue of the transition matrix is relevant to magnetic relaxation. Therefore, ac magnetic susceptibility, for a given local field, has been calculated using Debye's formula

$$\chi - \chi_{hf} = \frac{\chi_{eq} - \chi_{hf}}{1 + i\omega/\Gamma}, \quad (3)$$

FIG. 5. Magnetic susceptibility for $\omega/2\pi = 15$ Hz and $T = 5$ K as a function of the longitudinal applied field. Data points represent experimental results for a single crystal of Mn_{12} acetate (see Ref. 8), lines are the theoretical values. The high frequency component χ_{hf} has been subtracted from the experimental data because it vanishes in our calculations.

where χ_{eq} is the equilibrium susceptibility, and then broadened with a distribution of local fields. The calculated susceptibility is compared in Fig. 5 to some experimental data. The quantitative agreement is gratifying.

The magnetic properties of the Mn_{12}ac molecular cluster were studied by complex susceptibility and specific heat measurements. Extensive ac susceptibility measurements done under a magnetic field on good quality single crystals and zero field powder sample specific heat results indicate that the usual uniaxial Hamiltonian, as well as the recently proposed fourth order corrections, are not enough to account for all the observations. Very low temperature specific heat data indicate the presence of zero field splitting of the ground state which is much larger than expected. Finally, specific heat measurements done under a magnetic field permitted us to observe and measure the lattice spin relaxation by calorimetric methods with time constants that are in agreement with the magnetic relaxation measurements. © 1998 American Institute of Physics. INTRODUCTION

Molecular crystals containing isolated magnetic clusters have recently renewed the attention to the relaxation properties of small magnetic particles,^{1,2} because they permit the macroscopic observation of single nanomagnetic particle properties, avoiding complications due to size and orientation distribution existing in traditional small magnetic particle systems. In particular, for the most studied one, Mn_{12}ac , it was possible to observe unusual magnetic quantum phenomena at the nanoscopic scale: thermally assisted quantum tunneling and field tuned resonant tunneling.³⁻⁵ These ferromagnetic clusters formed by 12 Mn atoms coupled by antiferromagnetic superexchange interaction are embedded in large molecules with the formula $[\text{Mn}_{12}(\text{CH}_3\text{COO})_{16}(\text{H}_2\text{O})_4\text{O}_{12}]$, being well isolated from each other.⁶ A $S=10$ spin configuration is stabilized below 20 K with a high anisotropy³ responsible for the slow superparamagnetic relaxation of the magnetization observed below 4 K.⁷ The high uniaxial crystalline anisotropy splits the $S=10$ levels in 10 doublets with $m_s = \pm 10$ lowest in energy. The simplest spin Hamiltonian in zero field may be written as

$$H = -DS_z^2 - g\mu_B \mathbf{S} \cdot \mathbf{B} \quad (1)$$

with the splitting parameter D first determined by electron paramagnetic resonance (EPR) spectroscopy⁸ to be $D/k_B = 0.86$ K, so the total anisotropy energy barrier is $\Delta E/k_B = 86$ K. At very low temperatures, each cluster of this system can be considered as blocked in one of the two "macroscopic" degenerated states $|m_s = \pm 10\rangle$. Classically, the switching between those states occurs only by a thermal activation process over the barrier. The magnetic relaxation time was found to follow an Arrhenius Law:⁷

$$\tau = \tau_0 e^{\Delta E/k_B T} \quad (2)$$

with $\Delta E/k_B = 64$ K and the prefactor $\tau_0 = 2.4 \times 10^{-7}$ s. Below 2 K, the relaxation time deviates from the Arrhenius law, becoming temperature independent⁹ and being attrib-

uted to quantum tunneling of magnetization (QTM). Other evidence of QTM came from the unusual increase of the relaxation time for small fields.³ More recently, magnetization curves in oriented powder⁴ and single crystal⁵ showing steps at regular field intervals were interpreted, using the Hamiltonian Eq. (1), as thermally assisted resonant quantum tunneling at fields where the energy of opposite spin orientation crossed. Recently, we showed that the expected specific heat Schottky contributions from Eq. (1) were not in agreement with the experimental results above 3 K.¹⁰ Better agreement was obtained using a Hamiltonian including fourth order terms in spin operators, proposed recently by Barra *et al.*¹¹ Still a considerable linear term, as well as a low temperature specific heat contribution, remained to be explained and will be addressed by this article from extended specific heat measurements down to 0.1 K.

EXPERIMENTAL RESULTS AND DISCUSSION

We will now present new ac susceptibility measurements as function of temperature and external field at various frequencies (from 1 Hz to 10 kHz). The temperature dependence of the relaxation data, obtained from the maxima of

FIG. 1. Arrhenius fit for the relaxation time for the Mn_{12}ac in zero field. Inset shows real (line with symbol) and imaginary susceptibility at selected frequencies.

^{a)}Electronic mail: mnovak@if.ufrj.br.

FIG. 2. Susceptibility as function of external field along c axis. Inset shows a sketch of the anisotropy energy barrier as function of orientation of the spin with the c axis.

the imaginary part of the susceptibility,³ is shown in Fig. 1. The total effective energy barrier obtained by fitting Eq. (2), $\Delta E/k_B = 65$ K, and $\tau_0 = 1.5 \times 10^{-7}$ s depend slightly on the temperature range considered due to the small downward curvature. The slope of this plot, $d \ln \tau/d(1/T)$, may be considered as an effective energy barrier (E_{ef}) which changes with T . In the high frequency (and temperature) range, E_{ef} reaches 95 K and τ_0 about 10^{-10} s, closer to the usual attempt frequency of traditional superparamagnets. This reflects the decreasing importance that thermally activated quantum tunneling (TAQT) between the middle of the barrier states have as the temperature is raised. Around 10 K most of the spins switch by classical over barrier thermal activation which is much faster than TAQT.

In Fig. 2 we show typical curves of ac susceptibility data obtained under an external field along the easy c axis which permitted us to determine the resonant field at which level crossing occurs. From several curves done from 4.3 up to 10 K and using various frequencies we were able to determine up to four resonances with values of the applied field $H = 0.0, 4.3, 8.8$, and 12.9 kOe, and independent of temperature. Those fields are close to the ones found at lower temperatures in magnetization measurements^{5,12} but have a much narrower width. χ' shows a maximum with a Lorentzian shape, whereas χ'' shows either a maximum or a local minimum at the resonant fields, depending if the temperature is below of above the blocking temperature for the measurement frequency. The main resonance occurs at a zero field and has a half width around 600 Oe. This is much larger than the expected linewidth for tunneling resonance,¹³ and reflects the presence of a distribution of local fields of different origins: hyperfine, dipolar, and demagnetizing.

The specific heat measurements were done using the semiadiabatic method from 1.4 up to 25 K in a home made cryostat and from 0.1 to 1.5 K in another calorimeter attached to the mixing chamber of a dilution refrigerator. Each data was collected using a 1 min heat pulse and monitoring the temperature drift for several minutes before and after the heat pulse with automated data acquisition systems. Three different contributions to the total specific heat are expected:

FIG. 3. Specific heat data in zero field in the whole temperature range. Calculated Schottky contribution using energy levels given by Eq. (4) (full line). The splitting of the $m_s = \pm 10$ ground state is represented by the broken line. The straight line at lowest T is the hyperfine T^{-2} fit. Inset shows the resultant c/T T^2 plot after subtracting the two Schottky contributions, showing a negligible linear term.

lattice c_l , hyperfine c_h , and magnetic Schottky c_s :

$$c = c_l + c_h + c_s. \quad (3)$$

The hyperfine contribution is negligible above 3 K. We analyze the data above this temperature by calculating the magnetic Schottky contribution due to the zero field splitted energy levels given by the recently proposed Hamiltonian and parameters of Ref. 10:

$$H = DS_z^2 + AS_z^4 + B(S_+^4 + S_-^4). \quad (4)$$

The contributions that are left are c_l and an extra one below 3 K which cannot be attributed to pure hyperfine interactions within the Mn atoms. In Fig. 3 we show the experimental results and the calculated Schottky specific heat as the full line. A T^3 Debye term could be extracted above 3 K, leaving a considerable linear contribution with a small rounded maximum at 1.89 K. This is not expected by Eq. (4), which gives a ground state splitting too small to explain this contribution. Recent neutron scattering experiments¹⁴ which agree with this last Hamiltonian reported the existence of a distinct energy level around 0.2 THz which would correspond to a ground state splitting of about 5 K. Our data below 3 K can be explained if we invoke a 4.5 K splitting of the ground state and assuming that only 17% of the total clusters contribute to this anomaly. This also eliminates the unexplained apparent linear term in the specific heat above 3 K,¹⁰ as shown in the inset of Fig. 3. At the lowest temperature the line is the expected T^{-2} contribution due to the Mn nuclear hyperfine interaction. The 17% factor may be related to a fast relaxation process present in this system also corresponding to a fraction of the total magnetization. In fact, recent ac susceptibility measurements show that this second relaxation process follows roughly an Arrhenius behavior down to 2 K with relaxation time extrapolated to 1 K of the order of 50 s. The origin of this splitting cannot be related to a combination of hyperfine and dipolar fields, as it corresponds to an equivalent field of 3.3 kOe. Estimates of this local field add up to about 0.5 kOe and have a distribution

which depends on the magnetization of the sample. This is in agreement with the ac susceptibility resonance at a zero field in Fig. 2. The local fields are also responsible for the non-negligible specific heat between 0.3 and 0.8 K, unaccounted by pure Mn hyperfine interactions or by the ground state splitting. Another possibility for the ground state splitting may be due to canting of individual Mn spins within each cluster occurring at a temperature above 2 K, a process which is not cooperative, thus not giving rise to any sharp anomaly in the specific heat.

Finally, we consider the effect of an external magnetic field, leading to a field dependent Schottky anomaly. For simplicity we use the simple Hamiltonian in Eq. (1). Although the system is not in equilibrium, one may consider in quasiequilibrium and count only the states that are accessible in the measuring time. The system may be regarded as two sets of spins with the same energy level spacing, one with the $+m_s$ or down states and the other with the $-m_s$ or up states separated by the anisotropy barrier. In the zero field, the thermal excitations take place within each side of the double well and from one side to the other with a smaller probability due to tunneling. At a low enough temperature, when the switching time is much longer than the typical measuring time (at 3 K the time for spin reversal is 300 s), the two sets of energy levels become independent from each other, reducing the number of the accessible states to about one half. In the presence of a small magnetic field, as long as the two sets of levels continue being independent, the specific heat should be almost the same as the field produces small changes in the level spacing within each well. Figure 4 shows the specific heat data in a field of 3 kOe as well as in zero field. An excess contribution due to the field becomes apparent above 3 K, which corresponds to the blocking temperature for the experimental time window. At lower temperatures the relaxation time is much longer than the time scale of our measurements, so each cluster spin remains blocked in either side of the barrier, and the specific heat remains almost the same as in the zero field. As the temperature is increased and the relaxation time becomes comparable to the experimental time, the states in both sides become progressively accessible as the spins unblock and the specific heat increases. In fact, in the temperature evolution after each heat pulse an extra exponential time dependence appears from which we could determine what we call the lattice-spin relaxation time, having a fair agreement with the magnetic relaxation time constant as can be seen in the inset of Fig. 4.

FIG. 4. Specific heat of Mn_{12}ac powder in 0.3 kOe and a zero applied field. Inset shows lattice spin relaxation time data and spin lattice relaxation from magnetic measurements as straight line.

In conclusion, low temperature specific heat measurements on Mn_{12}ac clusters show clearly a splitting of the ground state and also allowed the observation of lattice spin relaxation.

Proton spin-lattice relaxation (NSLR) measurements have been performed in two molecular copper magnetic rings containing 6 and 8 spins ($S = 1/2$), respectively, in an almost coplanar arrangement in order to probe the spin dynamics of the spins in the ring. The NSLR results obtained in the Cu6 and Cu8 rings as a function of temperature and of applied magnetic field are compared with previous results of NSLR of ^1H in the iron(III) rings Fe6 and Fe10 ($S = 5/2$). At room temperature, common features are found in the spin dynamics while at low temperature, when correlation effects become important, important differences are observed in the rings depending on the kind of coupling between magnetic spins (ferromagnetic or antiferromagnetic) and on the spin value S .

I. INTRODUCTION

The recent successes in synthesizing solid lattices of weakly coupled magnetic molecular building blocks has opened up the possibility of studying experimentally magnetism at the mesoscopic scale.¹ The study of molecules is of particular interest, where strongly interacting spins are arranged in almost coplanar ring configurations, a situation which can be easily modeled theoretically.²

Molecular clusters containing 6 and 10 iron(III) spins ($S = 5/2$) in almost coplanar ring configuration have been recently investigated by magnetic susceptibility³ and proton NMR.⁴ We present here ^1H NMR results in a new set of rings containing 6 and 8 copper ions, respectively, also in almost coplanar configuration. The copper ions have $S = 1/2$ and thus these rings represent mesoscopic scale "quantum" spin rings. The comparison of the ^1H NMR in the quantum copper rings with the ^1H NMR in iron(III) ($S = 5/2$) "classical" rings appears particularly interesting. The two new Cu rings investigated here are the cluster $[(\text{PhSiO}_2)_6\text{Cu}_6(\text{O}_2\text{SiPh})_6] \cdot 6\text{EtOH}$ which will be denoted as Cu6⁵ and the cluster $[\text{Cu}_8(\text{dmpz})_8(\text{OH})_8] \cdot 2\text{C}_6\text{H}_5\text{NO}_2$ which will be denoted as Cu8.⁶ In the Cu6 ring, the coupling between nearest neighbor Cu^{2+} spins is ferromagnetic (FM) with coupling constant $|J|/k_B = 60.5$ K and the ground state configuration is magnetic with total spin $S = 3$.⁵ In the Cu8 ring, on the other hand, the coupling is antiferromagnetic (AM) with a large $|J|/k_B$ value ($\cong 800$ K) and the ground state is a $S = 0$ nonmagnetic singlet.⁷

II. RESULTS AND DISCUSSION

The NMR measurements were performed on polycrystalline powder samples synthesized as described in Refs. 5 and 6. The proton nuclear spin-lattice relaxation rate (NSLR) T_1^{-1} was measured with a standard Fourier transform pulse NMR spectrometer by monitoring the recovery of the nuclear magnetization following a short sequence of saturating radio frequency pulses.^{4,8} The recovery was nonexponential due to the presence of many inequivalent protons in the irradiated NMR line. The NSLR reported here was obtained from the initial decay of the magnetization. T_1^{-1} is thus a weighted average over all protons.⁴

The protons in the molecules are coupled to the Cu^{2+} spins via nuclear-electron dipolar interactions. The fluctuations of the Cu^{2+} spins generate a time dependent hyperfine field at the proton site which induces nuclear spin-lattice relaxation. Thus, measurements of NSLR allow one to probe the spin dynamics of the spins in the ring.

The general expression for the NSLR due to the coupling of the protons to the fluctuating Fe or Cu spins is^{9,10}

$$\frac{1}{T_1} = \frac{(\hbar \gamma_n \gamma_e)^2}{(4 \pi g^2 \mu_B^2)} k_B T \left[\frac{1}{4} \sum_q A^\pm(q) \chi^\pm(q) f_q^\pm(\omega_e) + \sum_q A^z(q) \chi^z(q) f_q^z(\omega_n) \right], \quad (1)$$

where $\omega_n = \gamma_n H$ and $\omega_e = \gamma_e H$ are the Larmor frequencies of the proton and of the free electron, respectively, g is the Lande's factor, μ_B is the Bohr magneton, k_B is the Boltzman constant, $\chi(q)$ is the generalized q -dependent spin susceptibility, and $f_q(\omega)$ is the spectral density of the collective spin fluctuations.⁹ The coefficients $A^\pm(q)$ and $A^z(q)$ are the Fourier transforms of the spherical components of the product of

^{a)}Also at: Department of Physics "A. Volta," Unita INFM di Pavia, Via Bassi 6 I27100 Pavia, Italy

^{b)}Electronic mail: borsa@ameslab.gov

two dipole-interaction tensors⁹ describing the hyperfine coupling of a given proton to the Cu magnetic moments. The symbol \pm and z refer to the components of the Cu spins transverse and longitudinal with respect to the quantization direction which is here the external magnetic field.

In the high temperature approximation, Eq. (1) can be approximated as

$$\frac{1}{T_1} = \frac{(\hbar \gamma_n \gamma_e)^2}{(4\pi g^2 \mu_B^2)} k_B T \chi(q=0) \left[\frac{1}{2} A^\pm \Phi^\pm(\omega_e) + A^z \Phi^z(\omega_n) \right], \quad (2)$$

where $\Phi^\alpha(\omega) = \sum_q f_q^\alpha(\omega)$ are the Fourier transforms of the auto-correlation functions (CF) of the transverse ($\alpha = \pm$) and longitudinal ($\alpha = z$) components, respectively, of the local Cu spin. The enhancement of T_1^{-1} at low fields is similar to what is observed in one dimensional paramagnetic chains where it results from the diffusive behavior at a long time of the correlation function in 1D Heisenberg systems.⁹ In a finite size ring, one expects that the spin auto-correlation function has an initial fast decay with correlation frequency $\Gamma_D \propto |J|/\hbar$ followed by a much slower decay due to the cyclic boundary conditions of the ring, terminating with a cut-off frequency Γ_A which depends on anisotropic terms in the spin hamiltonian.^{8,9,11} Thus we write⁸

$$\frac{1}{T_1} = \frac{(\hbar \gamma_n \gamma_e)^2}{(4\pi g^2 \mu_B^2)} k_B T \chi(q=0) \left[\frac{1}{2} A^\pm \frac{\Gamma_A}{(\omega_e^2 + \Gamma_A^2)} + \frac{1}{2} \frac{A^\pm}{\Gamma_D} + A^z \left(\frac{1}{\Gamma_D} + \frac{1}{\Gamma_A} \right) \right] = \frac{A}{B + H^2} + C. \quad (3)$$

The experimental results about the dependence of the NSLR on the external magnetic field at room temperature in Fig. 1 were fitted by using the second part of Eq. (3) with H measured in Tesla and $1/T_1$ in ms^{-1} (see curves in Fig. 1). For Fe6, we have not done a fit of the data due to the large experimental uncertainty. However, as can be seen in Fig. 1(a), the data for Fe6 can be accounted for by the same theoretical curve which fits the Fe10 data.

Since the exchange coupling J is much greater than the anisotropy, one expects $\Gamma_D \gg \Gamma_A$. Thus from the fitting parameters in Eq. (3), we can estimate values for Γ_A , A^\pm , and A^z from experiments with the assumption that A^\pm and A^z are of the same order of the magnitude. The estimated values are shown in Table I together with the values of Γ_D calculated from the spin diffusion model, i.e., $\Gamma_D = (2\pi J/\hbar)[S(S+1)]^{-1/2}$.⁸ The calculated values of Γ_D support the assumption $\Gamma_D \gg \Gamma_A$. The value of Γ_A for Fe10 (Fe6) corresponds to $\hbar\Gamma_A/k_B = 0.6$ K very close to the anisotropy energy deduced from Fe6 susceptibility measurements.³ The values of Γ_A in Table I do not change appreciably for the different rings indicating that the anisotropy is small for all the Heisenberg rings. Finally the values of the hyperfine coupling constants are of the correct order of structure data. In fact, A^\pm and A^z are products of two dipolar interaction tensor components and thus of the order of r^{-6} where r is the distance between a proton and a Cu (Fe) electron spin. We conclude that the main feature of the high temperature spin

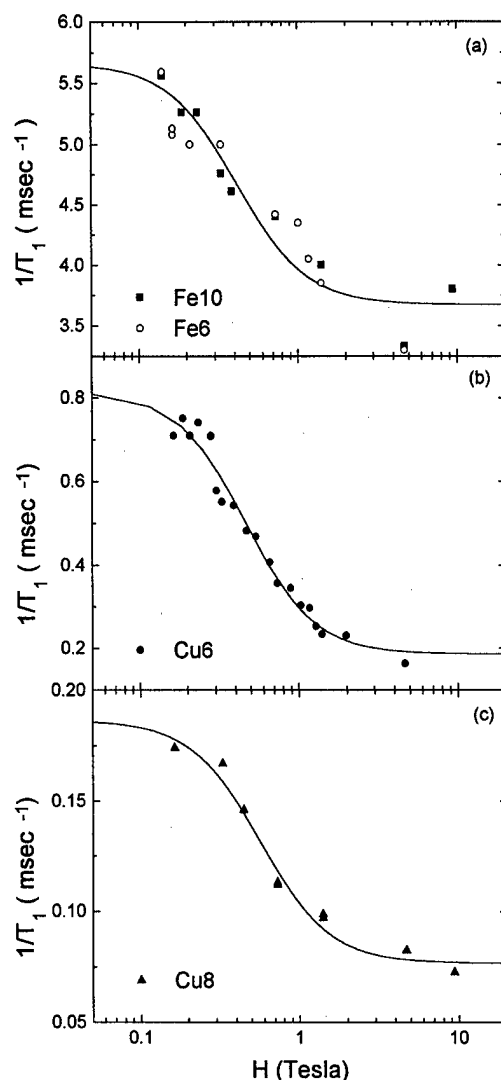

FIG. 1. Proton average nuclear spin-lattice relaxation rate (NSLR) vs applied magnetic field at room temperature for the two classical iron(III) rings (a) and for the two quantum copper rings (b) and (c). The curves are the results of the fit to Eq. (3) with the parameters in Table I.

dynamics is the persistence at long times of the spin-spin correlation function due to the periodic boundary conditions in the ring. This feature seems to be common to all rings.

The temperature dependence of the NSLR is a sensitive probe of correlation effects of the spins in the ring and/or the presence of the gap from the ground state to the first excited state due to the finite size of the spin system. Contrary to the high temperature case, the low temperature spin dynamics displays a variety of behaviors according to the type of ring. We present here preliminary results with a qualitative discussion. A complete study including ^{63}Cu NMR results will be published elsewhere.⁷

The temperature dependence of the ^1H NSLR is shown in Fig. 2. The temperature dependence of the classical AF ring Fe6 from Ref. 4 is reported in Fig. 2(c) for the purpose of comparison. In comparing the data for the AF rings in Figs. 2(b) and 2(c), it is noted that in both cases the NSLR displays an exponential drop at low temperature due to the condensation of the system in its $S=0$ nonmagnetic ground state separated by a gap Δ/k_B from the first excited triplet

TABLE I.

Ring	Γ_D (10^{12} rad/s) (calc.)	Γ_A (10^{10} rad/s)	A^\pm (10^{45} cm $^{-6}$)	A^z (10^{45} cm $^{-6}$)	J/k_B (K)	$T_\chi(q=0)$ ($T=300$ K) (emu/mole of magnetic ion)
Fe10 (Fe6)	5.33 (11.05)	7.5 ± 1.5	5.3 ± 2	5 ± 0.5	13.8 (28.6)	3.2 ± 0.2 (2.5 ± 0.2)
Cu6	6.86	8.2 ± 0.7	13 ± 3	2 ± 0.4	60.5	0.47 ± 0.03
Cu8	90.6	9.9 ± 3	15 ± 4	5.2 ± 1	~ 800	0.085 ± 0.01

state. For Fe6, the gap, derived from susceptibility measurements, is $\Delta/k_B = 20$ K³ while for Cu8, $\Delta/k_B \cong 600$ K.⁷ These values are consistent with the NSLR results although somewhat different values for the gap are derived from NSLR.^{4,7} For Fe6, one observes an enhancement of $1/T_1$ at low T which is not present in the susceptibility data [see Fig. 2(c) and inset] and is thus arising from a slowing down of the

spin fluctuations as the system becomes more correlated, i.e., a decrease of Γ_D in Eq. (3). For Cu8, it is not possible to say if the enhancement of $1/T_1$ is present since one should extend the measurement at higher temperature where the system decomposes.

Another comparison can be made between the FM ring Cu6 and the AF ring Fe6 in Figs. 2(a) and 2(c). In the temperature range of 300–50 K, the NSLR increases in the FM case and it decreases in the AF case indicating that the spin dynamics is dominated by the behavior of the static response function $T\chi(q=0)$ in Eq. (3). In both cases, the NSLR has a critical divergence for T approaching the short range “ordering” temperature $|J|/k_B$ as shown in Fig. 2. (For Cu6, $|J|/k_B = 60.5$ K⁵ while for Fe6 $|J|/k_B = 28.8$ K.^{3,4} Finally, although in both Fe6 and Cu6 the NSLR drops as $T \rightarrow 0$ due to the gap, in the case of the Cu6 FM ring, there remains sizeable nuclear relaxation due to the degeneracy of the $S=3$ ground state. A quantitative analysis of the low temperature nuclear relaxation should give information about the excitations in the $S=3$ ground state.

Analysis of electron paramagnetic resonance experiments in colossal magnetoresistance materials

D. L. Huber

Department of Physics, University of Wisconsin-Madison, Madison, Wisconsin 53706

An analysis is given of recent electron paramagnetic resonance (EPR) experiments in manganite materials displaying colossal magnetoresistance behavior. These experiments have established that in highly homogeneous samples characterized by a single resonance line, the EPR linewidths above the critical region associated with the paramagnetic-ferromagnetic transition are inversely proportional to $T\chi(T)$, where χ denotes the susceptibility. This behavior indicates that the linewidth does not reflect a coupling to the lattice vibrations but rather is caused by a spin-only mechanism. The possibility that the linewidth arises from the dipolar interaction is assessed using an effective interaction model. On the basis of the model calculation, it is concluded that the dipolar interaction is probably too weak to account for the observed broadening and that the linewidth most likely arises from tetragonal and orthorhombic distortions of the octahedral crystal field at the sites of the Mn ions. The EPR linewidth in samples with very low concentrations of Mn^{4+} ions is expected to vary with temperature as $[T\chi_{\text{sp}}(T)]^{-1}$, where $\chi_{\text{sp}}(T)$ is the susceptibility of the ferromagnetically coupled spin polaron. By measuring the temperature dependence of the linewidth, one may be able to determine the temperature dependence of the polaron susceptibility. © 1998 American Institute of Physics. I. INTRODUCTION

Understanding the behavior of Mn-based materials showing colossal magnetoresistance (CMR) properties is a challenge for both experimentalists and theorists. Although most of the attention has been focused on the effect of applied magnetic field and temperature on the conductivity, there is much to be learned from studies of the spin-dependent properties through measurements of the static and dynamic spin susceptibilities. This is a consequence of the fact that the dominant magnetic interaction is the double exchange (DE) coupling, which is associated with the "hopping" of electrons between Mn ions. In the simple picture, it is these mobile electrons that are the source of the anomalous transport.

Experimental studies of CMR materials have been hampered by the difficulty of obtaining high-quality samples. This has been a particular problem for electron paramagnetic resonance (EPR) measurements, which are unusually sensitive to sample inhomogeneities. Recently, the results of a series of EPR measurements have been reported by Granado *et al.*¹ that provide direct evidence of the effect of sample homogeneity on the EPR spectra. The results of similar measurements on high-quality samples of $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ have been also been reported by Lofland *et al.*² Of particular interest here are the measurements of the EPR linewidth of a highly homogeneous, ceramic sample of $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ presented in Ref. 1. The authors found that the linewidth varied as $A/T\chi(T)$, where χ denotes the susceptibility and A is a temperature-dependent parameter $\approx 7200 \text{ Oe K}$. This behavior was observed over the range $300 \text{ K} \leq T \leq 900 \text{ K}$ ($T_c = 270 \text{ K}$). The absence of a temperature dependence to the linewidth beyond that associated with the product $T\chi(T)$ was interpreted as indicating that the linewidth arose from a spin-only mechanism, in contrast to earlier results where the

linewidth was attributed to a spin-phonon mechanism.³⁻⁵ Such an interpretation was based on measurements which found the parameter A to be a linear function of the temperature indicative of a one-phonon mechanism.⁶

It is beyond the scope of this paper, and probably premature, to characterize EPR measurements that do *not* show a linewidth varying with temperature as $[T\chi(T)]^{-1}$ as being influenced by sample inhomogeneity. Rather, we take the point of view that measurements that *do* find that A approaches a constant value at high temperatures are directly probing a spin-only relaxation mechanism for the total spin. In this paper, we will discuss possible microscopic spin-only mechanisms for the relaxation of the moment in CMR materials. We will also comment briefly on the importance of EPR measurements on samples with very low concentrations of Mn^{4+} ions.

II. ANALYSIS

Due to the role of the double exchange mechanism, a quantitative analysis of the EPR linewidth even in the high-temperature limit is a formidable problem. Since we are mainly interested in a qualitative analysis of the linewidth in the $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ sample described in Ref. 1, we will approximate the DE interaction by a nearest-neighbor Heisenberg interaction, with an effective spin determined by the weighted averages of the spins of the Mn^{3+} and Mn^{4+} ions and an exchange integral inferred from the paramagnetic Curie temperature, $T_{\text{cp}} \approx 370 \text{ K}$. Support for such an approximation comes from inelastic neutron scattering studies in $\text{La}_{0.7}\text{Pb}_{0.3}\text{MnO}_3$, where the magnon dispersion curves over much of the Brillouin zone were fit with the corresponding Heisenberg spin-wave dispersion relation obtained from an exchange interaction with an effective spin equal to 1.85 and a nearest-neighbor coupling J equal to 27.6 K .⁷

In a similar spirit, we equate the paramagnetic Curie temperature of $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ to the standard expression

$$k_B T_{cp} = (2/3) z J S_{\text{eff}} (S_{\text{eff}} + 1), \quad (1)$$

where $z (=6)$ is the number of nearest neighbors and S_{eff} is an effective spin defined to ensure that the effective Curie constant $(1/3)g^2\mu_B^2 S_{\text{eff}}(S_{\text{eff}}+1)$ is equal to the weighted average of the Curie constants of the Mn^{3+} and Mn^{4+} ions, $(1/3)g^2\mu_B^2\{6(1-x) + (15/4)x\}$. Using this expression with $x=1/3$, one obtains $S_{\text{eff}}(S_{\text{eff}}+1)=5.25$ and an effective nearest-neighbor Heisenberg interaction J equal to 17.6 K. Since the $\text{La}_{0.7}\text{Pb}_{0.3}\text{MnO}_3$ sample had a Curie temperature of 355 K, whereas the measured Curie temperature of the $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ sample was 270 K, our value for J , when scaled by the ratio $(355/270)$, is equal to 23.1 K, which is reasonably close to the value inferred for the Pb sample, 27.6 K, indicating a measure of consistency between the high- and low-temperature analyses. A more stringent test of the analysis is provided by a calculation of the zero-temperature spin stiffness D . For a Heisenberg ferromagnet with nearest-neighbor interactions, one has $D=2JSd^2$, where d is the nearest-neighbor separation 3.9 Å. Replacing S by the average spin, $S_{\text{av}}=2(1-x) + (3/2)x=11/6$ ($x=1/3$), one obtains $D=85 \text{ meV Å}^2$. This value is within a factor of 2 of the stiffness obtained from inelastic neutron scattering studies of $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$, where it was found that $D=155 \text{ meV Å}^2$ for a sample with $T_c=250 \text{ K}$.⁸

With the parameters of the effective nearest-neighbor Heisenberg Hamiltonian in hand, one can proceed to calculate the high-temperature limit of the EPR linewidth using the well-known technique of spectral moments.⁹ We first consider the dipolar mechanism. In the exchange narrowed limit, the Lorentzian linewidth (half width at half height) δ is expressed approximately as $(\pi/2)^{1/2}(M_2)^{3/2}(M_4)^{-1/2}$,¹⁰ where M_2 and M_4 denote the second and fourth moments of the line-shape function. Integrating over angles and specializing to a simple cubic lattice with nearest-neighbor interactions, we obtain the result

$$\delta \approx 1.5g^4\mu_B^4[S_{\text{eff}}(S_{\text{eff}}+1)]^{1/2}d^{-6}J^{-1}, \quad (2)$$

where d , as before, is the distance between nearest-neighbor Mn ions. With the values given previously for J and S_{eff} one has $\delta \approx 3 \text{ Oe}$. This value is to be compared with the high-temperature limit of the linewidth in $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$ inferred from the ΔH_{pp} data in Ref. 1 and the corresponding paramagnetic Curie temperature, 370 K. One finds $\delta \approx 1800 \text{ Oe}$. Although the theoretical estimate for δ was obtained from an effective Heisenberg Hamiltonian, we believe that the discrepancy of a factor of 600 between the two values of δ is too large to be attributed to the approximations and can be explained only by the existence of an alternative relaxation mechanism. This will be discussed in the following section.

III. DISCUSSION

As noted above, the estimate of the dipolar contribution to the high-temperature limit of the EPR linewidth is too small by a factor of 600, indicating the need to consider

alternative mechanisms. A possible clue to the origin of the linewidth lies in the failure so far to observe a resonance signal in stoichiometric LaMnO_3 . Stoichiometric LaMnO_3 has orthorhombic symmetry at room temperature,¹¹ whereas at room temperature, oxygen-annealed $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$ can have cubic symmetry for $x>0.2$.¹² Since the high-temperature limit of the dipolar linewidth in LaMnO_3 is calculated to be on the order of 10 Oe (the Néel temperature in orthorhombic LaMnO_3 is 140 K and $S=2$, so the corresponding value for the nearest-neighbor Heisenberg exchange integral in the mean-field approximation is 6 K), the absence of a resonance in LaMnO_3 is attributed to the presence of second-order [i.e., DS_z^2 and $E(S_x^2 - S_y^2)$] anisotropy terms in the spin Hamiltonian for the Mn^{3+} ions that come from the interplay of spin-orbit coupling and the noncubic components of the crystal field. Such terms are not invariant under rotation of the total spin. As a consequence, they can lead to the fast relaxation of the spin moment giving rise to a resonance that is too broad to be detected. [The cubic components of the crystal field are thought not to play an important role since the ten energy levels of the lowest manifold of the Mn^{3+} (d^4) ion in an octahedral field are degenerate to first order in the spin-orbit interaction.¹³] Even in the case of the cubic phases of $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$, we expect local departures from octahedral symmetry due to the presence of Mn^{3+} , which is a Jahn-Teller ion. We hypothesize that it is the noncubic crystal symmetry or the local Jahn-Teller distortions (dynamic and static) from cubic symmetry that is responsible for the anomalously large high-temperature linewidth in $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$ and other Mn-based CMR materials.¹⁴ Nevertheless, the single-ion mechanism is weaker than it is in the stoichiometric material presumably because of an enhanced effectiveness of the DE relative to Heisenberg superexchange interaction in producing an exchange narrowed linewidth, a point that will be addressed in a separate publication. The effectiveness of the DE is also consistent with the presence of only a very weak (and thus, presumably, not intrinsic) resonance in the cubic Mn^{4+} compound CaMnO_3 .¹⁵ Only when there are substantial concentrations of both Mn^{4+} and Mn^{3+} ions is there an intense resonance signal. Also, we note that while we have emphasized the importance of single-ion mechanisms, one cannot yet rule out anisotropic exchange couplings as a contributor to the relaxation.

The discussion in the preceding paragraph points to the importance of measurements of the EPR linewidth in samples with very small concentrations of Mn^{4+} ions.¹⁴ In such systems, we expect that a spin-polaron picture will be appropriate. We predict that at high temperatures, the linewidths in these materials will vary as $A'/T\chi_{\text{sp}}(T)$, where $\chi_{\text{sp}}(T)$ denotes the susceptibility of the spin polaron, which we expect to be proportional to $(T-T_{\text{sp}})^{-1}$, where T_{sp} denotes an effective spin-polaron paramagnetic Curie temperature reflecting the strength of the ferromagnetic correlations. In contrast, the parameter A' should have about the same magnitude it has in $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$, assuming a similar microscopic relaxation mechanism. It is also possible that the random motion of the spin polaron can play a role in the relaxation of the moment of the cluster. If this is the case,

one might expect a motionally narrowed linewidth with a temperature dependence proportional to $\exp[E_a/k_B T]$, where E_a denotes a thermal activation energy for the polaron hopping.

Finally, we would like to stress that although the dipolar interaction does not appear to make a significant contribution to the EPR linewidth at high temperatures, it can be important near the ferromagnetic critical temperature, where short-range anisotropic terms become relatively less important.¹⁶ Should this be the case (which would require that the transition be second order, or at least weakly first order), one would expect that the product $T\chi(T)\Delta H$ would increase as $T \rightarrow T_c$ from the paramagnetic side. Because of the pronounced effect of the applied field on the phase transition, definitive measurements of dynamical critical effects should be made in zero field.

¹⁴The issue of static versus zero-point dynamic Jahn–Teller distortions depends on the time scale. The EPR linewidth is proportional to the time integral of the correlation function $\langle [S_x^T, H_{\text{anis}}](t)[H_{\text{anis}}, S_x^T](0) \rangle$, where S_x^T denotes the x component of the total spin and H_{anis} is the anisotropic part of the Hamiltonian. If this correlation function decays at a rate that is rapid in comparison with the characteristic frequencies of the dynamic Jahn–Teller effect, then the distinction between the static and dynamic linewidth mechanisms disappears. Such would appear to be the case for the DE interaction in the manganites where the characteristic time scale of the correlation function is set by the hole bandwidth.

A novel method for quantitative study of domain reversal behavior

Sug-Bong Choe and Sung-Chul Shin^{a)}

Department of Physics, Korea Advanced Institute of Science and Technology, Taejeon 305-701, Korea

A novel method to quantitatively analyze the domain reversal behavior has been adopted to understand the total-thickness-dependent domain reversal behavior in Co/Pd multilayers. The wall-motion speed and the nucleation rate were simultaneously determined by analyzing serial domain images observed using a real-time domain observation system. Using this method, sensitive decrement of the wall-motion speed with increasing total multilayer thickness has been found to be responsible for the contrasting reversal behavior in Co/Pd multilayers. © 1998 American Institute of Physics. [S0021-8979(98)49211-9]

I. INTRODUCTION

Magnetization reversal in magnetic thin films is of interest for applications as well as fundamental understanding of magnetism. The contrasting reversal behaviors in numerous systems have been reported to occur by either the nucleation dominant process or the wall-motion dominant one.¹⁻⁴ Interestingly, the reversal phenomena were found to be very strongly dependent on the total film thickness.^{5,6} These reversal behaviors have been analyzed by the thermally activated relaxation model based on the magnetization viscosity curve⁷ and also, compared with the theoretical predictions using micromagnetic simulations.⁸ Recently, we have developed a novel method to quantitatively analyze the magnetization reversal behavior by considering both the nucleation and wall-motion processes based on the time-dependent domain patterns.⁹ In this article, we have applied the novel method to investigate the contrasting magnetization reversal behavior in Co/Pd multilayers with varying the total multilayer thickness.

II. DESCRIPTION OF THE PRESENT METHOD

Details of the model have been described elsewhere.⁹ Briefly, the model of magnetization reversal is proposed by using the time-dependent domain patterns based on circular domains. In the model, the reversed domains expand at all domain boundaries by the wall-motion speed V and simultaneously, new domains are formed by the nucleation rate R per unit time and unit area during the magnetization reversal from the initially saturated state. Then, the expansion of the reversed domain area da in time dt is given by

$$da = lVdt + \pi r_0^2 R(s-a)dt, \quad (1)$$

where l is the domain boundary length, r_0 is the characteristic radius of nucleation, s is the total area under examination, and a is the area of reversed domains. Similarly, the increment of the domain boundary length dl in time dt becomes

$$dl = 2\pi Vdt + 2\pi r_0 R(s-a)dt. \quad (2)$$

Then, the wall-motion speed V and the nucleation rate R are explicitly given by

$$\left. \begin{aligned} V &= (a' - r_0 l' / 2) / (l - \pi r_0) \\ R &= (l l' / 2\pi - a') / (l - \pi r_0) r_0 (s - a) \end{aligned} \right\}, \quad (3)$$

where a' and l' denote the first derivation of a and l , respectively. Thus, the wall-motion speed V and the nucleation rate R can be simultaneously determined by measuring the reversed domain area $a(t)$ and the domain boundary length $l(t)$.

A real-time domain observation system has been adopted to measure the reversed domain area and the domain boundary length during the magnetization reversal. Serial domain images of 256 frames with 10 frames per second were obtained using a modified magneto-optic Kerr microscope capable of $\times 1000$ magnification with an objective of 0.9 N.A. and equipped with advanced digital video processing. The image, composed of 200×160 pixels with the unit size of 164×164 nm, was initially obtained in 256 gray levels and then, intensified by noise filtering and black-and-white image extraction processes. Then, the reversed domain area $a(t)$ and the domain boundary length $l(t)$ were determined by counting black and white cells, and by edge determining algorithms, respectively, for each image at the corresponding time t . The measurement error due to the geometric difference between the theory based on circular domains and the observation based on square cells is decreased with increasing domain radius, and does not exceed 50% for the single pixel domain of 82 nm radius.

The magnetization reversal behavior of Co/Pd multilayered system has been investigated. Samples of $(2 \text{ \AA} \text{ Co} / 11 \text{ \AA} \text{ Pd})_n$ with varying the number of repeats n , were prepared on glass substrates by e -beam evaporation under the base pressure of 1.0×10^{-6} Torr at the ambient temperature. The multilayered structure was achieved by alternatively exposing the substrate to the two e -beam sources with typical deposition rates of 0.3 $\text{\AA}/\text{s}$ for Co and 0.5 $\text{\AA}/\text{s}$ for Pd. The layer thickness was controlled within a 4% accuracy by the thickness-control technique using real-time thickness measurement.¹⁰

III. RESULTS AND DISCUSSION

All samples in this study had perpendicular magnetic anisotropy and showed Kerr hysteresis loops of unit squareness. Figure 1 shows the hysteresis loops of Kerr rotational angles measured at the wavelength of 4000 \AA for the type I

^{a)}Electronic mail: scshin@sorak.kaist.ac.kr

FIG. 1. Hysteresis loops of Kerr rotational angle measured at 4000 Å of (a) the type I sample of $(2 \text{ Å Co}/4 \text{ Å Pd})_{10}$ and (b) the type II sample of $(2 \text{ Å Co}/4 \text{ Å Pd})_{23}$. Coercivities, H_c , are 1.0 and 1.5 kOe, respectively.

sample of $(2 \text{ Å Co}/11 \text{ Å Pd})_{10}$ and the type II sample of $(2 \text{ Å Co}/11 \text{ Å Pd})_{23}$. The samples have coercivities, H_c , of 1.0 and 1.5 kOe, respectively.

In Fig. 2, we show the magnetization viscosity curves of types I and II samples under various reversing applied fields as denoted in the figures. The curves were measured by averaging the intensity of the images observed by the microscope at low magnification and normalizing by the intensities between the initially saturated state and the completely reversed state. The abscissa axis is also normalized by the half relaxation time τ which is sensitively dependent on the strength of an applied field. The normalized curves for a given sample are completely coincident with each other, but the curves between the samples are quite contrasting. The viscosity curve of the type I sample shown in Fig. 2(a) exhibits initially a slow decay, with accelerated reversal with time. This curve has a typical shape of thermally activated relaxation, with low nucleation rate and fast domain-wall speed.⁷ In contrast, the type II sample shown in Fig. 2(b) exhibits initially a fast decay and then, slow down to an equilibrium state. This shape can be interpreted as a typical behavior of thermally activated relaxation with large nucleation rate and slow domain-wall speed.

Serial domain images of magnetization reversal were taken by the real-time observation system under an applied field of $0.8 H_c$ for each sample. Figure 3 shows the typical

FIG. 2. Viscosity curves under several reversing applied fields for (a) the type I sample and (b) the type II sample. The curves were normalized by the maximum Kerr intensity and the half relaxation time τ .

FIG. 3. Typical domain patterns during magnetization reversal of (a) the type I sample and (b) the type II sample under reversing applied fields of $0.8 H_c$ for the corresponding samples. The number of percent denoted at the bottom of each frame is the areal fraction of the reversed domain.

domain reversal patterns of types I and II samples having the same areal fractions of reversed domains. The areal expansion by the wall-motion process is clearly observed in the type I sample as shown in Fig. 3(a), while the stripe growth by the nucleation process is seen in the type II sample as shown in Fig. 3(b).

Quantitative analysis on the contrasting reversal behaviors of these samples were carried out. The reversed domain area $a(t)$ and the domain boundary length $l(t)$ measured from the domain reversal patterns of types I and II samples, are plotted in Fig. 4. The lines with squared symbols in each plot of Fig. 4 show the reversed domain area $a(t)$ and they are very consistent with the magnetization viscosity curves shown in Fig. 2.

FIG. 4. Plots of the fractional area of reversed domain $a(t)/s$ and the domain boundary length $l(t)$, with respect to time t , measured from the domain images during the magnetization reversal under the applied field of $0.8 H_c$ for (a) the type I sample and (b) the type II sample.

TABLE I. The mean values of the wall-motion speed V , the nucleation rate R , and the ratio V/R of the first 20% of reversal under an applied field of $0.8 H_c$ for types I and II samples.

Sample ID	V ($\mu\text{m s}^{-1}$)	R ($\mu\text{m}^{-2} \text{s}^{-1}$)	V/R (μm^3)
Type I	1.34	0.41	3.27
Type II	0.06	0.08	0.74

The wall-motion speed V and the nucleation rate R of each sample were determined by using the present method. The first derivatives $a'(t)$ and $l'(t)$ in Eq. (3) were obtained by the finite-difference method¹¹ and the characteristic radius r_0 was set to 82 nm corresponding to the pixel size of our observation. The values of wall-motion speed V , the nucleation rate R , and the ratio V/R of types I and II samples, are listed in Table I. It is quite understandable that the wall-motion speed of the wall-motion dominant sample of type I is larger than that of the nucleation dominant sample of type II, but it is unexpected that the nucleation rate of the type I sample is found to be also larger than that of the type II sample. However, the reversal behavior is determined by a counterbalance between the wall-motion process and the nucleation process, and the change in the wall-motion speed between the samples is quite a bit larger than the change in the nucleation rate: the wall-motion speed decreases more than a factor of 20, while the nucleation rate decreases only a factor of 5. Thus, the type I sample shows wall-motion dominant reversal with a large ratio of 3.27 between the wall-motion speed and the nucleation speed, while the type II sample exhibits nucleation dominant reversal with a small ratio of 0.74. Therefore, one might conclude that the contrasting reversal behavior in this system is caused by the sensitive change in the wall-motion speed overcoming the nucleation rate.

It is worthwhile to note that the present result is quite contrastive compared with the previous one in Ref. 9: the contrasting reversal behavior in Co/Pd multilayers having a different thickness of the Co sublayers with a fixed number

of repeats was caused by the change in the nucleation rate. The previous result was understood to be caused by the change in the magnetic properties among the samples of different Co-sublayer thickness, but the present result is probably dominated by the change in the wall-pinning effect due to the different structural irregularities between the samples of different total multilayer thickness.

IV. CONCLUSION

A novel method to quantitatively analyze the magnetization reversal behaviors of magnetic films has been adopted to investigate the reversal behavior of Co/Pd multilayered films. The wall-motion speed and the nucleation rate were simultaneously determined from serial domain images captured by a real-time domain observation system. With increasing total thickness in the Co/Pd multilayered system, the wall-motion speed was much more sensitively decreased than the nucleation rate. Thus, it could be concluded that the contrasting reversal behavior observed in this system is mainly caused by the variation in the wall-motion speed.

A microscopic theory is employed to investigate the spin wave spectra in metamagnetic materials that consist of ferromagnetically ordered layers, with the intralayer ferromagnetic exchange interactions being much stronger than the weak antiferromagnetic interaction between adjacent layers. © 1998 American Institute of Physics. [S0021-8979(98)29911-7]

Theoretical and experimental studies of surface spin waves in ordered magnetic materials have been the focus of considerable interest for many years. Many of these works have been concerned with the spin wave properties, at the low-temperature regime, of Heisenberg ferromagnets and antiferromagnets, mainly in terms of their dispersion relations, thermodynamics, and Green functions (for a review see Refs. 1–3). Besides, as a result of recent advances in fabrication techniques, spin wave excitations in magnetic superlattices of impressive quality have been also extensively studied by considering the nature of the solutions for the appropriate wave field in each film. They are then linked together through appropriate boundary conditions and with the assistance of Bloch's theorem. The surfaces and interfaces in these layered structures play an important role in the properties of the entire system and, indeed, most of the interesting properties of these excitations are due to the surface and interface effects.^{4–7}

In this article we extend previous studies in this subject by considering the propagation of surface spin waves in metamagnets which present nonuniaxial anisotropy. The metamagnetic materials consist of ferromagnetically ordered layers, with the intralayer ferromagnetic exchange interactions being much stronger than the weak antiferromagnetic interaction between adjacent layers. We consider also the presence of a weak external magnetic field \mathbf{H} applied perpendicular to the layers. In the regime of low temperatures and for small values of an external magnetic field \mathbf{H} the adjacent layers of the metamagnet material order are antiparallel to one another, giving the antiferromagnetic (AFM) phase. On the other hand, for larger \mathbf{H} , enough to overcome the interlayer antiferromagnetic coupling, the overall ordering is ferromagnetic (FM phase). The spin wave analysis is more straightforward in this case since the direction of net spin alignment is the same on both sublattices (this case is not treated here).

We consider that the metamagnet has single-ion anisotropic energy. This is a fine structure energy of an ion under the influence of the crystalline electrical field, to which the spin-orbit coupling and intraatomic magnetic interactions among the spins contribute. The forms of the anisotropic spin Hamiltonian is determined from the point symmetry

around the ion, and is assumed to be a function of the direction cosines of the magnetization vector \mathbf{M} with respect to the crystallographic axes. In the absence of an external magnetic field, \mathbf{M} lies in the direction in which the free energy is minimal. This direction is called the axis of “easy” magnetization, and usually we call the related anisotropic field as uniaxial (“easy-axis”) single-ion anisotropy. When an external magnetic field is applied, the magnetization vector deviates to a new direction at which the torque exerted by the external magnetic field balances the torque originating in the anisotropic energy. Thus a nonuniaxial (“easy-plane”) single-ion anisotropy component appears. We take into account in this article both types of anisotropic field.

Rather than using a “continuum” approximation, as was done in a recent paper⁸ dealing with some nonuniaxial effects in magnetic superlattices, we develop here a microscopic theory, taking into account surface effects in a semi-infinite metamagnet that has a (001) surface and occupies the half space $z > 0$. The method of calculation is the same as the one presented in previous papers.^{9,10}

The spin Hamiltonian for nonuniaxial metamagnets can be written as:^{10,11}

$$H = \sum_{i,j} J_{ij} (\mathbf{S}_i \cdot \mathbf{S}_j + \sigma S_i^z S_j^z) - \frac{1}{2} \sum_{i,i'} J'_{ii'} (\mathbf{S}_i \cdot \mathbf{S}_{i'} + \sigma' S_i^z S_{i'}^z) - \frac{1}{2} \sum_{j,j'} J'_{jj'} (\mathbf{S}_j \cdot \mathbf{S}_{j'} + \sigma' S_j^z S_{j'}^z) + H_z + H_A, \quad (1)$$

where the Zeeman Hamiltonian is given by

$$H_z = -g \mu_B H \left(\sum_i S_i^z + \sum_j S_j^z \right), \quad (2)$$

and the anisotropic Hamiltonian is expressed by

$$H_A = -D \left(\sum_i (S_i^x)^2 + \sum_j (S_j^x)^2 \right) - F \left(\sum_i (S_i^x)^2 - (S_i^y)^2 \right) - F' \left(\sum_j (S_j^x)^2 - (S_j^y)^2 \right). \quad (3)$$

We suppose plane-wave solutions of the type $S_i^+ = s_n(k_{\parallel}) \exp[i(\mathbf{k}_{\parallel} \cdot \boldsymbol{\rho} - \omega t)]$ and $S_i^- = r_n(k_{\parallel}) \exp[i(\mathbf{k}_{\parallel} \cdot \boldsymbol{\rho} - \omega t)]$ where n stands for the layer index. Using these assumptions

^{a)}Electronic mail: ela@dfte.ufrn.br

in the Heisenberg equation for the spin operator S_i^+ , with $\hbar=1$, we get the following set of coupled equations for the spin wave amplitudes:

for $n=1$:

$$[E_- + (1 + \sigma)Sv(0)]s_1 - Sv(k_{\parallel})s_2 + 2FS\eta^{1/2}r_1 = 0, \quad (4)$$

$$[E_- + (1 + \sigma)Sv(0) - 2\omega]r_1 - Sv(k_{\parallel})r_2 + 2FS\eta^{1/2}s_1 = 0; \quad (5)$$

for $n=2m+1$; $l=i$:

$$E_-s_{2m+1} - Sv(k_{\parallel})s_{2m+2} - Sv(-k_{\parallel})s_{2m} + 2FS\eta^{1/2}r_{2m+1} = 0, \quad (6)$$

$$(E_- - 2\omega)s_{2m+1} - Sv(k_{\parallel})s_{2m+2} - Sv(-k_{\parallel})s_{2m} + 2FS\eta^{1/2}r_{2m+1} = 0; \quad (7)$$

for $n=2m$; $l=j$:

$$E_+s_{2m} - Sv(k_{\parallel})s_{2m+1} - Sv(-k_{\parallel})s_{2m-1} - 2F'S\eta^{1/2}r_{2m} = 0, \quad (8)$$

$$[E_+ - 2\omega]r_{2m} - Sv(k_{\parallel})r_{2m+1} - Sv(-k_{\parallel})r_{2m-1} + 2FS\eta^{1/2}s_{2m} = 0, \quad (9)$$

where $E_{\pm} = \omega - g\mu_B H \pm E_0 \pm 2(1 + \sigma)Sv(0)$, $E_0 = E_0(k_{\parallel}) = g\mu_B H_A + (1 + \sigma')Su(0) - Su(k_{\parallel})$, and we have defined the Fourier transforms of the intralayer bulk exchange interaction by

$$u(k_{\parallel}) = \sum_i J'_{ii'} \exp[i\mathbf{k}_{\parallel} \cdot (\mathbf{r}_i - \mathbf{r}_{i'})] \\ = \sum_j J'_{jj'} \exp[i\mathbf{k}_{\parallel} \cdot (\mathbf{r}_j - \mathbf{r}_{j'})], \quad (10)$$

while for the interlayer exchange interaction we consider

$$v(k_{\parallel}) = \sum_{\delta} J_{ij} \exp(i\mathbf{k}_{\parallel} \cdot \delta), \quad (11)$$

where δ is a vector joining the i sites in layer n to that j sites in layer $n+1$. After a tedious algebraic manipulation of these equations, we get the following matrix set of equations:

$$(A + \Delta_1)F = \Theta G, \quad (12)$$

$$(A^* + \Delta_1^*)G = \Theta^* F. \quad (13)$$

Here F and G are infinite-dimensional column matrices, whose elements are specified by $F_m = s_{2m}$ and $G_m = r_{2m}$. Also, A is a trigonal matrix given by

$$A = \begin{bmatrix} d & -\tau^{-1} & 0 & 0 & \cdots \\ -\tau & d & -\tau^{-1} & 0 & \cdots \\ 0 & -\tau & d & -\tau^{-1} & \cdots \\ 0 & 0 & -\tau & d & \cdots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}, \quad (14)$$

while the matrix $\Theta = \delta I + \Delta_2$ ($\Theta^* = \delta^* I + \Delta_2^*$), where I is the identity matrix. The matrix Δ_i ($i=1$ or 2) describes the perturbing effect of the surface, and is expressed by

$$(\Delta_i)_{m,m'} = \Delta_i \delta_{m,1} \delta_{m',1}; \quad i=1,2. \quad (15)$$

The surface spin wave equation corresponds to

$$\det(I - \Theta^* A_1^* \Theta^{-1} A_1) = 0, \quad (16)$$

where

$$A_1 = A + \Delta_1; \quad A_1^* = A^* + \Delta_1^*, \quad (17)$$

whose solutions are

$$[(\xi_1 - t\xi_3)(\Gamma + \beta) - \xi_2\xi_4 + (s - ht)\xi_3\xi_4 + \xi_5 \\ - gt\xi_1(\Gamma - gt)] \cdot \bar{M} = 0, \quad (18)$$

where

$$s = -\tau b; \quad t = \tau^2 a, \\ h = -\tau^{-1} b; \quad g = \tau^{-2} a, \quad (19) \\ \Gamma = 1 - 2a - c; \quad \beta = \Delta_2 a / (\delta + \Delta_2).$$

In all these matrix equations, the terms d , τ , δ , δ^* , Δ_i , Δ_i^* ($i=1$ or 2), and ξ_j ($j=1-5$) are complicated expressions involving the physical parameters of the metamagnet materials. Their full algebraic expressions can be found elsewhere.¹² Also, \bar{M} is the determinant:

$$\bar{M} = \begin{vmatrix} \Gamma & h & g & 0 & 0 & 0 & \cdots \\ s & \Gamma & h & g & 0 & 0 & \cdots \\ t & s & \Gamma & h & g & 0 & \cdots \\ 0 & t & s & \Gamma & h & g & \cdots \\ 0 & 0 & t & s & \Gamma & h & \cdots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \ddots \end{vmatrix}. \quad (20)$$

If we choose $\bar{M} \neq 0$, the surface spin-wave dispersion relation is then given by the first term of Eq. (18).

On the other hand, the bulk spin-wave dispersion relation can be found using the ansatz $M \cdot u = 0$, where u is a column matrix with elements $u(n)$ representing a mode amplitude. Then,

$$tu_{n-2} + su_{n-1} + \Gamma u_n + hu_{n+1} + gu_{n+2} = 0. \quad (21)$$

By choosing the solutions such that $u(n) = \alpha x^n$ (for x unknown), using the definitions of a , b , and τ , and denoting $y = \tau x$, we get

$$a(y^2 + y^{-2}) - b(y + y^{-1}) = -\Gamma. \quad (22)$$

This is a fourth-degree equation for y . The roots of this equation, together with the assumption that $x = \exp(2ik_z c_0)$, where $2c_0$ is the distance between even (or odd) adjacent layers, yield the following bulk dispersion relations:

$$\cos(2k_z c_0) = \frac{1}{2\tau} \left(\pm \sqrt{(d + d^*)^2 + 4(dd^* - \delta\delta^*) + 16} \right. \\ \left. + (d + d^*) \right). \quad (23)$$

Equation (23) is an implicit dispersion relation. It can be obtained by supposing that the roots of Eq. (22) occur at pairs, and that the pairs are complex conjugate one of the other. In compact form they can be written as

$$[\tau \cos(2k_z c_0)]^2 - (d + d^*)\tau \cos(2k_z c_0) - (dd^* - \delta\delta^*) - 4 \\ = 0. \quad (24)$$

FIG. 1. Crystallographic arrangements of Fe^{2+} ions (solid circles) in the ferromagnetically ordered layers for FeBr_2 and FeCl_2 . The nearest and next-nearest intralayer neighbors to the ion labeled 1 are those labeled 2 and 3, respectively. The crosses and open circles represent the positions of the ions in the adjacent layers above and below the planes for FeCl_2 .

The solutions of the above expression give the bulk modes for the spin waves, and they are valid in the antiferromagnetic phase.

We now apply the surface and bulk (for completeness) dispersion equations to determine the spin-wave spectra for the specific cases of FeBr_2 and FeCl_2 . They have their crystallographic arrangements of magnetic ions as depicted in Fig. 1. Both materials have the same trigonal arrangements of magnetic Fe^{2+} ions within each ferromagnetically ordered layer. They differ, however, in the stacking arrangements of the layers. In FeBr_2 , the Fe^{2+} ions in one layer are vertically situated above and below those in the adjacent layers, although in FeCl_2 the layers are staggered with respect to one another. The crosses and open circles in Fig. 1 represent the positions of the ions in the adjacent layers above and below the planes.

Figure 2 shows the dispersion relation for bulk and surface spin waves in FeBr_2 in the AFM phase. We take as the applied magnetic field $g\mu_B H = 1.6 \text{ cm}^{-1}$. We plot the frequency ω (in units of 10 cm^{-1}) against $k_x a$ (here we consider $k_{\parallel} = k_x$). The physical parameters used here are those described in Ref. 10, with the nonuniaxial anisotropic field $F = F' = 2 \text{ cm}^{-1}$. Comparison of this spectrum with those in which there is no nonuniaxial component of the anisotropic field (Fig. 2 in Ref. 10) shows that the bulk band is now split, giving rise to two separated bands limited by the curves $k_z a = 0$ and $k_z a = \pi$. Besides, there are also two well defined surface modes (shown by the dashed lines) below and between these bulk bands. The inset gives a better insight into this situation (observe that the bulk bands are shown as shaded).

FIG. 2. Dispersion relations of bulk (shaded areas) and surface (dashed lines) spin waves in FeBr_2 in the AFM phase as a function of the in-plane wave vector $k_x a$ for the applied magnetic field $g\mu_B H = 1.6 \text{ cm}^{-1}$.

The spin-wave spectra for the FeCl_2 metamagnet (not shown here) is qualitatively quite the same of that for FeBr_2 , but the low-frequency surface branch is very close to the first bulk band. This fact, which is due to their different crystal structure, presents an additional difficulty in probing this mode experimentally.

Appropriated experimental techniques for studying the spin-wave spectrum in metamagnets would include light scattering spectroscopy of the Raman and Brillouin types and magnetic resonance. For FeBr_2 , the light scattering technique may be more suitable, since our theoretical predictions indicate that at least one branch (the low-frequency one) of the surface spin waves is well separated in frequency (even in the absence of the nonuniaxial anisotropic field) from the bulk modes.

Exchange narrowing effects in the EPR linewidth of Gd diluted in Ce compounds

Anomalous thermal behavior on the EPR linewidths of Gd impurities diluted in Ce compounds has been observed. In metals, the local magnetic moment EPR linewidth, ΔH , is expected to increase linearly with the temperature. In contrast, in $\text{Ce}_x\text{La}_{1-x}\text{Os}_2$ the Gd EPR spectra show a nonlinear increase. In this work, the mechanisms that are responsible for the thermal behavior of the EPR lines in $\text{Ce}_x\text{La}_{1-x}\text{Os}_2$ are examined. We show that the exchange interaction between the local magnetic moments and the conduction electrons are responsible for the narrowing of the spectra at low temperatures. At high temperatures, the contribution to the linewidth of the exchange interaction between the local magnetic moments and the Ce ions has an exponential dependence on the excitation energy of the intermediate valent ions. A complete fitting of the EPR spectra for powdered samples is obtained. © 1998 American Institute of Physics. [S0021-8979(98)39911-9]

I. INTRODUCTION

During the last two decades Ce compounds have been extensively studied and many of them show anomalies typical of intermediate valence systems.¹ Electron paramagnetic resonance (EPR) spectra of magnetic ions diluted in Ce compounds allow us to study locally the influence of the intermediate valent Ce ions. In normal metals, the thermal behavior of the local moments EPR linewidth, ΔH , is linear and described by the Korringa mechanism.² In contrast, in $\text{Ce}_x\text{A}_{1-x}\text{Pd}_3$ ($\text{A}=\text{Ag}, \text{Y}$) and $\text{Ce}_x\text{La}_{1-x}\text{Os}_2$ the Gd spectra shows a nonlinear increase of ΔH in the temperature range $4.2 < T < 300$ K, and a strong dependence on the Ce concentration.^{3,4} At low temperatures (T) the slope $d(\Delta H)/dT$ is smaller than in the isostructural non-IV compounds MPd_3 ($\text{M}=\text{Sc}, \text{Y}, \text{La}$)⁵ and LaOs_2 ,⁴ however, at high temperatures the resonance line is strongly broadened and the slope asymptotically approaches the value measured on them. Then, to describe this abnormal behavior of linewidth other mechanisms different from the Korringa are necessary.

It was demonstrated⁶ that at high temperatures, the indirect exchange interaction between the local magnetic and the Ce $4f$ electrons has an appreciable contribution to the linewidth of the magnetic impurities at high temperature. The Ce interconfigurational fluctuations are transferred via the Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction to the Gd site as an effective alternating magnetic field, which relaxes the Gd spins. However, this mechanism is not sufficient to describe the low temperature behavior of the Gd linewidth. It is well known^{7,8} that the Gd EPR spectra shows a resolved fine structure at low T , which is narrowed due to

the exchange interaction between local magnetic moments and conduction electron when the temperature is increased. Then, for the correct description of the thermal behavior of the Gd spectra it is necessary to include not only the intermediate valence effects but also the narrowing mechanism. The goal of this work is to calculate the EPR spectra of Gd diluted in $\text{Ce}_x\text{La}_{1-x}\text{Os}_2$ including the both mechanisms.

II. THEORETICAL ANALYSIS

To obtain the EPR absorption, the transverse dynamic susceptibility of the local magnetic moments coupled to the conduction electrons is necessary. The susceptibility, including the crystal field interaction, can be obtained using the projector formalism in the Liouville space.⁹ Normally the EPR experiments are performed at a concentration that the conduction electrons static susceptibility is much smaller than those of the local moments, then, in this approximation, the susceptibility for the system in the nonbottleneck regime can be written as follows

$$\chi^+(\omega) \approx 1 - \omega_0 \left[\sum_{M,M'} P_M(\Omega^{-1})_{M,M'} \right], \quad (1)$$

where $\Omega_{M,M'}^{-1}$ is the transition matrix, the quantum numbers M and M' describe the various Zeeman states ($M, M' = -S, -S+1, \dots, S-1$) associated to the $S=7/2$ Gd spin and P_M are transition probabilities associated to the $M \leftrightarrow M+1$ transition and can be written as:

$$P_M = C_M \exp^{M\hbar\omega_0/kT} / \sum_M C_M \exp^{M'\hbar\omega_0/kT}, \quad (2)$$

where $C_M = S(S+1) - M(M+1)$ and k is the Boltzmann constant. The elements of the transition matrix for kT large compared to $\hbar\omega_0$ are expressed by the formula

^{a)}On leave from Departamento de Física, Universidade Estadual Paulista, Av. Engenheiro Luiz E. Coube S/N, 17033-360 Bauru-SP, Brazil.

$$\begin{aligned}\Omega_{M,M'} = & (\hbar\omega_0/g\mu_B - H - H_M)\delta_{M,M'} - i\Delta H_{res}\delta_{M,M'} \\ & - i\frac{1}{2}bC_{M'}(2\delta_{M,M'} - \delta_{M,M'}) \\ & - \delta_{M,M'+1} - \delta_{M,M'-1},\end{aligned}\quad (3)$$

where ω_0 is the microwave frequency, H is the variable external magnetic field, ΔH_{res} is the temperature independent residual linewidth of the various fine structure lines, b is the Korringa parameter, μ_B is the Bohr magneton, and H_M is the resonance field of the Gd $M \rightarrow M+1$ transition. As we can see, the transition matrix is a tridiagonal matrix where the diagonal elements contain the linewidth of each resonance line and the resonance field. The upper and lower diagonals terms represent the fluctuation rates of the local moment between two consecutive resonance frequencies.

In a cubic environment the fine structure spectra is given by

$$\begin{aligned}H(\pm\frac{7}{2} \leftrightarrow \pm\frac{5}{2}) &= H_0 \mp (1-5\phi)b_4, \\ H(\pm\frac{5}{2} \leftrightarrow \pm\frac{3}{2}) &= H_0 \pm (1-5\phi)b_4, \\ H(\pm\frac{3}{2} \leftrightarrow \pm\frac{1}{2}) &= H_0 \pm (1-5\phi)b_4, \\ H(+\frac{1}{2} \leftrightarrow -\frac{1}{2}) &= H_0,\end{aligned}\quad (4)$$

where b_4 is the crystal field parameter for the Gd ion, ϕ is given by

$$\phi = \sin^2 \theta \cos^2 \theta + \sin^4 \theta \cos^2 \varphi \sin^2 \theta \quad (5)$$

and θ and φ are spherical coordinates of the applied magnetic field H with respect to the axes of the crystal.

As it was shown previously,^{7,8} for the LaSb:Gd and CePd₃:Gd, the spin-spin interaction between Gd ions has an important role in the calculation of the resonance spectra. In both cases was found that when the spin-spin interaction is not taken into account the narrowing in the theoretical spectra occurs at higher temperatures than in the experiment, the transition $1/2 \leftrightarrow 1/2$ does not appear in the theoretical spectra in the intermediate temperature range, however, it appears in the experiment, and the experimental linewidth of the single line at high temperatures is smaller than the calculated one. The discrepancies between theory and experiment can be overcome by introducing this interaction. Unfortunately, no theoretical calculation which takes spin-spin interaction into account exists at present. We shall introduce the spin-spin interaction in a phenomenological way.^{7,8} This can be done by adding to the transition matrix elements the term:

$$\Omega_{M,M'}^{ex} = i\frac{H_{ex}}{P_M}(1 - \delta_{M,M'}) - i\frac{6H_{ex}}{P_M}\delta_{M,M'}, \quad (6)$$

where H_{ex} is the exchange-field parameter. The transition matrix has some properties that must be satisfied for this additional term. First, $P_M \text{Im}(\Omega_{M,M'})$ are the elements of a negative-definite symmetric matrix. This guarantees a positive energy absorption. Second, as the total spin commutes with the exchange Hamiltonian, the relation $\sum_M \Omega_{M,M'} = 0$ must hold. Since these two requirements are satisfied, we can believe that the additional term for the transition matrix describes the main effects of the spin-spin interaction. Because of the random distribution of the Gd ions, it is realistic to assume a distribution of H_{ex} . For the present calculations we

FIG. 1. Temperature dependence of the Gd linewidth for selected values of concentration x in $\text{Ce}_x\text{La}_{1-x}\text{Os}_2$. The full lines represent the theoretical results. The residual linewidths are not realistic and the data has been shifted to avoid curve overlap.

use a slightly modified Lorentzian distribution for the exchange field with a maximum at $H_{ex}=0$. The mean exchange field amounts to about 95 G and the distribution function was cut off at 1500 G.

III. THE LINEWIDTH

In our metallic host the impurity EPR linewidth calculations must consider the energy transfer between the impurity spin S , the spin of the host rare earth ions (Ce), the spins of the conduction electrons as well as the lattice, in the presence of static external magnetic field and a small alternating field. In the present work we shall assume that the system is in the unbottlenecked regime, i.e., the conduction electrons and the host magnetic ions are in equilibrium with the lattice. In addition we shall assume that the transverse susceptibility associated with the impurity at the impurity resonance frequency is much larger than those of the other spin systems at the same frequency. In this limit one can consider only the transverse magnetization, M_x , of the impurities and neglect the interaction of the rf field with the magnetic host ions and the conduction electrons. In other words, the magnetic host ions and the conduction electrons are "passive dissipative

TABLE I. Obtained parameters b, b_4, A, E_{ex} that fit the linewidth thermal behavior for Gd diluted in $\text{Ce}_x\text{La}_{1-x}\text{Os}_2$. E_{ex} (expt.) is the experimental value of E_{ex} to be taken as a comparison.

x	b [G/K]	b_4 [G]	A [G]	E_{ex} (theor.)	E_{ex} (expt.)
1.0	1.07	4.8	10 200	670	500
0.95	1.32	10.6	10 150	684	
0.9	3.5	9.0	9800	1243	

systems.” With these assumptions the impurity linewidth can be expressed as:

$$\Delta H = \Delta H_{res} + bT + \Delta_{IF}, \quad (7)$$

where ΔH_{res} is the residual linewidth, b is the usual Korringa contribution, originated from the impurity-conduction-electron exchange interaction, and Δ_{IF} is the impurity linewidth due to the exchange interaction with the Ce host ions.⁶ The last contribution arises from the RKKY coupling between the Ce and Gd ions, which transfers the Ce fluctuations to the Gd site. Ce ions fluctuate between the $4f^0$ and the $4f^1$ configurations. If we assume the $4f^0$ configuration as the ground state (with $J_z = 0$), the contribution of the excited $4f^1$ configuration to the impurity linewidth can be written as:

$$\Delta_{IF} = A e^{-E_{ex}/T}, \quad (8)$$

where E_{ex} is the energy required to delocalize a single electron from the Ce $4f^1$ configuration and A is an adjustable parameter defined in Ref. 6.

The resonance absorption P is calculated using the relation $P = [\text{Re}(\chi^+(\omega)) - \text{Im}(\chi^+(\omega))]$. To obtain the EPR linewidth of the powdered samples we have to integrate the absorption over all directions of the magnetic field.

IV. RESULTS AND DISCUSSION

Using the results above we calculate the total linewidth of the Gd resonance. Figure 1 shows the calculated and experimental linewidth of a $\text{Ce}_x\text{La}_{1-x}\text{Os}_2$ powdered sample, as a function of temperature for selected concentrations of Ce. The residual linewidth is sample dependent and it was not considered in the plot. To fit the data we adjust the parameters b , b_4 , A , and E_{ex} using the Monte Carlo simulated annealing. With this technique it is possible to obtain more accurate results than previous calculations with conventional methods.⁶⁻⁸ Comparing our theoretical results with the experimental data we can see that in all of the cases we got an excellent fit. According to our model, at low T the main contribution to the linewidth is originated in the usual Korringa mechanism and the exchange narrowing effects. At high temperatures the population of the excited Ce $4f^1$ configuration is increased, and the exponential contribution given by Δ_{IF} is the most important. The parameters used to fit the experimental data are shown in Table I. The analysis *a priori* of the exchange narrowing effects in this system is not easy because there do not exist a single crystal spectra to obtain by a direct measure the crystal field parameter, however, if we look for the spectra of $\text{Ce}_{0.8}\text{La}_{0.2}\text{Os}_2$ in Fig. 1(a) of Ref. 4 we can see clearly that the Dysonian type line does not fit the experimental result. The experimental spectra shows the typical broadening at low T due to the fine structure contribution, and these effects tend to be more important in higher Ce concentrations.⁸ If we compare the exchange narrowing effects for the present case with that in CePd_3 (Ref. 8) certainly the exchange narrowing effects are less important in the former one, due to the smaller crystal field parameter. Otherwise, its contribution is more important at lower temperatures than in CePd_3 because the higher Korringa parameter values collapse the spectra at lower tempera-

tures. It is necessary to point out that the minimization results show clearly a nonzero value for the crystal field parameter which reflects the importance of this mechanism. On the other hand, looking for the intermediate valence mechanism, the effect of the Ce concentration at high temperature seems clear. The increase in the excitation energy value when the Ce concentration is reduced agree with the interconfigurational fluctuation model.¹⁰⁻¹³ This model predicts an increasing on the excitation energy when we cross from the intermediate valence to the magnetic regime. On the other hand, the A value depends on the strength of the Ce fluctuation spectra and we can expect an increase with the Ce concentration. The small values of b obtained for high Ce concentrations (when compared with those of LaOs_2) agree with the experimental results of Ref. 4 at low T , with the prediction of the ‘‘hybridization hole’’ model³ for Gd diluted in CePd_3 powdered sample and with that obtained in Ref. 8 for the monocrystalline spectra of the same compound. This result agrees also with that obtained by Hirst¹² for low T , but not with the result obtained in Ref. 14, which predicts a higher value for b . However, the thermal behavior of the linewidth obtained by the latter authors agrees, at least qualitatively, with that obtained here. It is important to observe that in contrast to the hybridization hole model, here we have supposed a constant density of states as in a normal metal. The nonlinear contribution to the linewidth, at high T , according with the present model, is originated in the exchange interaction of the magnetic impurities with the Ce ions.

In conclusion, our calculations using the intermediate valence and exchange narrowing mechanism permit a quantitative description of the thermal behavior of Gd linewidths. Note that the values obtained for the excitation energy are, within the experimental error, close to that founded by Sereni *et al.*¹⁵ The agreement with experimental results supports our interpretation.

Magnetization as a function of field was measured in pulsed fields of up to 40 T at various temperatures along the principal axes of single crystal Nd₃Co. Along the *a* axis we observed metamagnetic transitions at fields of 1.9 and 4.5 T at 4.2 K. We also observed a sharp increase in the magnetic moment in applied fields between 9.5 and 14 T. Along the *b* axis a metamagnetic transition was observed at a field of 1.5 T at 4.2 K. Along the *c* axis we observed ferromagnetic behavior. The *H*-*T* (magnetic field and temperature) phase diagram was obtained using a superconducting quantum interference device magnetometer. © 1998 American Institute of Physics. I. INTRODUCTION

The intermetallic compounds, R₃Co (R: rare earth metals except Ce), crystallize in the orthorhombic Fe₃C-type structure (space group Pnma) in which R occupies two non-equivalent very low symmetry crystallographic sites, i.e., 4*c* (point group *m*) and 8*d* (point group 1).¹⁻⁵ In our previous study⁶ (of electrical resistivity, magnetic susceptibility and specific heat measurements), it was reported that Nd₃Co has three magnetic transitions at low temperatures (spin reorientation temperatures T_{R1} =8 K and T_{R2} =13 K, and Néel temperature T_N =25 K). We also reported two field induced metamagnetic transitions along the *a* axis (transition fields of H_{a1} =1.8 T and H_{a2} =4.5 T) and one transition along the *b* axis (transition field H_b =1.9 T) below 7 T at 1.5 K. We proposed a canted magnetic structure to explain the complex magnetization process in Nd₃Co.⁶ However, a field of 7 T is not enough to achieve the saturation moment. Thus we have measured the high field magnetization in a pulsed magnetic field of up to 40 T at various temperatures. Since there are many magnetic phases in Nd₃Co, we aim to determine a magnetic phase diagram for the *a* axis in applied magnetic fields of up to 5 T and for temperatures down to 5 K. In this article we report the saturation moments and the magnetic phase diagram.

II. EXPERIMENT

A single crystal of Nd₃Co was obtained by the Bridgman method with an alumina crucible in a high vacuum quartz tube. Details of the sample preparation are described in Ref. 7. The magnetization curves were obtained in pulsed magnetic fields of up to 40 T at 4.2, 12, 19, and 30 K along the principal axes of the orthorhombic structure. The magnetization curves in fields up to 5 T were measured by a superconducting quantum interference device (SQUID) magnetometer

at various temperatures. The temperature dependencies of the magnetic susceptibilities were measured by means of vibrating sample magnetometer (VSM).

III. RESULTS AND DISCUSSIONS

We measured the temperature dependence of the magnetic susceptibility along the *a*, *b*, and *c* axes in the temperature range from 4.2 to 300 K under a constant field of 1 T. Figure 1 shows a part of the susceptibilities. Above 150 K the susceptibilities obey the Curie-Weiss law and the paramagnetic Curie temperatures θ_a , θ_b , and θ_c along the *a*, *b*, and *c* axes were estimated to be 39.4, 28.7, and 34.6 K, respectively. The effective magnetic moments along the *a*, *b*, and *c* axes are 3.64, 3.60 and 3.60 μ_B , respectively. These values are in good agreement with the expected values 3.62 μ_B from the trivalent Nd ion. This suggests that the cobalt has no magnetic moment. It is difficult to determine the crystalline field parameters from the anisotropy in magnetic susceptibility because there are too many parameters

FIG. 1. Temperature dependence of the magnetic susceptibility of Nd₃Co in an external field of 1 T over the temperature range 4.2–100 K. The inset shows the temperature dependence of the magnetization at various magnetic fields obtained using a SQUID.

^{a)}Electronic mail: sato@physics.sci.ynu.ac.jp

FIG. 2. Magnetization curve along the *a* axis in fields up to 40 T at 4.2, 12, and 19 K in Nd₃Co.

related to the low symmetry sites denoted by monoclinic *m* and triclinic *l* point symmetry. The reciprocal susceptibility deviates from the Curie–Weiss law below 150 K. This deviation may be due to higher order crystalline electric field parameters in the Hamiltonian.⁸ The inset shows in detail the temperature dependence of the magnetization at various magnetic fields. T_{R1} , T_{R2} , and T_M are the critical points in the thermomagnetic curves.

Figure 2 shows the magnetization curves along the *a* axis at various temperatures. Metamagnetic transitions with hysteresis are seen in fields of 1.9 and 4.5 T at 4.2 K. These transitions are due to the reversals of antiferromagnetic components along the *a* axis of the canted moments in the 4*c* and 8*d* sites. We also observe a sharp increase in magnetization in the field range from 9.5 to 14 T at 4.2 K. The increase in moment is $0.4 \mu_B/\text{Nd ion}$. This is not due to a metamagnetic transition. This phenomenon originates from the sign of the second and fourth order anisotropic constants such as is seen in the magnetization along the $\langle 111 \rangle$ direction in Fe metal or along the hard axis in Tb metal.⁹ At 12 K, we found that a metamagnetic transition shifts to about 3 T, as well as 1 T at 19 K. The saturated moments, M_s , at 4.2, 12, and 19 K are estimated to be 2.82, 2.73, and $2.66 \mu_B/\text{Nd ion}$, respectively. The value of saturation magnetization M_s extrapolated to 0 K is $2.87 \mu_B/\text{Nd ion}$, which is obtained by means of the $1/H^2$ law. This value is 88% of the free ion value of $3.27 \mu_B/\text{Nd ion}$. This is a result of the strong magnetic anisotropy due to the crystalline electric field effect in this compound.

Figure 3 shows the magnetization curves along the *b* axis at various temperatures. A metamagnetic transition with hysteresis occurs at 1.9 T at 4.2 K. This transition is most likely due to reversal of the antiferromagnetic component along the *b* axis of the Nd ion in the 8*d* site. The transition fields decrease with increasing temperature. The saturated moments at 4.2, 12, 19, and 30 K are estimated to be 2.57, 2.52, 2.49, and $2.32 \mu_B/\text{Nd ion}$, respectively. The value of saturation magnetization along the *b* axis extrapolated to 0 K

FIG. 3. Magnetization curve along the *b* axis in fields up to 40 T at 4.2, 12, 19, and 30 K in Nd₃Co.

is about $2.57 \mu_B/\text{Nd ion}$. This value is 78% of the free ion value $3.27 \mu_B/\text{Nd ion}$.

Figure 4 shows the magnetization curves along the *c* axis at various temperatures. These magnetization curves suggest that the resultant magnetic moment along the *c* axis is the ferromagnetic. The Nd moments on both the 4*c* and 8*d* sites have ferromagnetic components in this direction. The saturated moments M_s at 4.2, 12, 19, and 30 K are estimated to be 2.34, 2.34, 2.32, and $2.27 \mu_B/\text{Nd ion}$, respectively. The value of saturation magnetization along the *c* axis extrapolated to 0 K is $2.34 \mu_B/\text{Nd ion}$. This value is 71% of the free ion value. This value is the most suppressed one among those of the three principal axes. This suppression of the saturation moment on all three axes indicates the easy axis of this crystal is not one of the principal axes on either of the two nonequivalent sites.

In order to determine a magnetic phase diagram, for the

FIG. 4. Magnetization curve along the *c* axis in fields up to 40 T at 4.2, 19, and 30 K in Nd₃Co.

FIG. 5. Phase diagram of the magnetic field H and temperature T along the a axis in Nd_3Co .

field of up to 5 T by SQUID magnetometer. Figure 5 shows the H - T phase diagram along the a axis, which obtained from the critical temperatures denoted T_{R1} , T_{R2} , and T_M in the inset of Fig. 1 and the critical fields H_{c1} , H_{c2} , and H'_{c2} in Fig. 2, respectively. The three transitions made by means of the specific heat measurement⁶ in zero magnetic field mentioned above are denoted as triangles in Fig. 5. In phase I, there is a ferromagnetic component along the c axis and antiferromagnetic components along the a and b axes, respectively. Above H_{c1} the metamagnetic transition occurs. Above H'_{c2} and H_{c2} , the second and third metamagnetic transitions occur along the a axis, denoted as phases II and

III, respectively. Phase II is a state in which ferromagnetic and antiferromagnetic components coexist along the a axis. The states of phases III and IV are unknown. Phase V is also a state in which ferromagnetic and antiferromagnetic components coexist along the a axis, however it is different from phase II. Phase VI is a field induced ferromagnetic state. Neutron diffraction measurements in a magnetic field are needed to clarify each magnetic state and we are currently undertaking such a study.

We report on a comparative study of the effects of Si doping and of external pressure on magnetism and related phenomena in $\text{Nd}(\text{Co}_{1-x}\text{Si}_x)_2$ and $\text{Ho}(\text{Co}_{1-x}\text{Si}_x)_2$ compounds. The lattice volume in the Ho system is almost composition invariable for x up to 0.1, whereas an increase of $\approx 6\%$ is observed in the Nd system. Si substitutions for Co cause a dramatic increase of T_C in the Ho system for $x \leq 0.075$ and a gradual reduction of T_C in Nd analogs, whereas the Co moment becomes suppressed for $x > 0.05$ in both cases. Negative pressure effects both on T_C and the Co magnetic moment, although quantitatively different, are found in both systems. Expected changes of electronic structure and their influence on the hierarchy of exchange interactions and formation of the Co moment are discussed. © 1998 American Institute of Physics. [S0021-8979(98)40011-2]

Co magnetism in RECo_2 (RE=rare-earth element) compounds is frequently studied with respect to the itinerant electron metamagnetism.¹⁻³ Materials with rare-earth atoms without 4*f* electrons, YCo_2 or LuCo_2 serve as archetypes of spin-fluctuation systems with a high T_{sf} and a nonmagnetic ground state. Magnetic fields above 60 T induce in these two compounds a metamagnetic state due to a sudden field-induced splitting of the Co majority and minority 3*d* subbands. The Co metamagnetic state may be induced in DyCo_2 , HoCo_2 , and ErCo_2 in zero external field employing a large exchange field due to ferromagnetically ordered 4*f* magnetic moments at T_C . This first-order phase transition is accompanied by a pronounced drop of the electrical resistivity,⁴ and a sudden volume expansion due to Co moment formation.

The larger lattice volume of light rare-earth counterparts like PrCo_2 or NdCo_2 allows less delocalized Co 3*d* states and the Co moment to form. The second-order phase transition at T_C is accompanied by resistivity and volume anomalies usual for metallic ferromagnets.⁴

The nearness of ferromagnetism in YCo_2 and LuCo_2 is manifest also by the substitutions of some *p* atoms, like Al, for Co driving these compounds towards ferromagnetism. The $\text{RE}(\text{Co}_{1-x}\text{Al}_x)_2$ were subjected by papers focused on spin-fluctuation^{2,5-7} and magnetovolume phenomena.^{3,8,9} Although the lattice volume in $\text{Y}(\text{Co}_{1-x}\text{Si}_x)_2$ and $\text{Lu}(\text{Co}_{1-x}\text{Si}_x)_2$ compounds is altered only slightly with increasing x up to 0.10, one also observes suppression of T_{sf} , enhancement of the low-temperature susceptibility, and reduction of the critical metamagnetic field. Ferromagnetism is, however, not reached.¹⁰⁻¹³ Various aspects of magnetism in $\text{RE}(\text{Co}_{1-x}\text{Si}_x)_2$ compounds with RE=Gd, Tb, Dy, Ho, and Er were studied as well.^{12,14,15} Strong enhancement of T_C with Si doping has been observed for the latter three cases. Negative pressure effects on T_C in the heavy-rare-earth RECo_2 compounds are reported.¹⁷ Here we report on effects of Si doping and of external pressure on magnetism in the $\text{Nd}(\text{Co}_{1-x}\text{Si}_x)_2$ and $\text{Ho}(\text{Co}_{1-x}\text{Si}_x)_2$ systems.

The $\text{Nd}(\text{Co}_{1-x}\text{Si}_x)_2$ and $\text{Ho}(\text{Co}_{1-x}\text{Si}_x)_2$ polycrystalline samples for $x \leq 0.15$ were produced by melting stoichiometric mixtures of pure metals under argon atmosphere and annealed at 950 °C for 50 h in vacuum. The x-ray diffraction revealed only the expected cubic C15 structure. The lattice volume in the Ho system is almost composition invariable but an increase of about 6% is observed in $\text{Nd}(\text{Co}_{1-x}\text{Si}_x)_2$ for x between 0 and 0.10.

The resistivity was studied on bar-shaped samples (size $\approx 1 \times 1 \times 7 \text{ mm}^3$) using the ac four-terminal technique. The compressibility and the thermal expansion were measured using microstrain gauges (Micro-Measurements Inc., SK-350) fixed on a plane sample surface. The strain gauges were calibrated using the relevant reference data on Cu and Fe. The pressure experiments were performed in a CuBe cell silica fixed hydrostatic pressure up to 9 kbar cooled in the He closed-cycle refrigerator. The pressure was measured *in situ* using a manganin pressure sensor.

The first-order magnetic phase transition at T_C in the Ho compounds is reflected in a resistivity drop $\Delta\rho$ (see Fig. 1) and an abrupt expansion of the lattice (Fig. 2). Usual "second-order-type" resistivity (Fig. 3) and thermal-expansion (Fig. 4) anomalies are exhibited by the Nd counterparts. The additional resistivity and expansion anomalies at T_R (≈ 17 and 42 K in HoCo_2 and NdCo_2 , respectively) are attributed to the reorientation of the easy-magnetization axis.^{16,17}

The resistivity in Ho compounds above T_C is strongly affected by a spin-disorder scattering on RE moments and by a conduction electron scattering on 3*d* spin fluctuations.¹⁸ When the 4*f* moments order ferromagnetically at T_C they produce a strong exchange field acting on the Co 3*d* states. Consequently, the 3*d* majority and minority subbands split, spin fluctuations at the Co sites quench and a metamagnetic state is induced by a first-order transition. The consequent reconstruction of the Fermi surface and the drastically suppressed conduction-electron scattering yield the huge resis-

FIG. 1. Temperature dependence of resistivity of $\text{Ho}(\text{Co}_{1-x}\text{Si}_x)_2$ for $x=0$ (in 1 and 5.9 kbar), 0.05 (in 1 and 7.1 kbar), and 0.075 (in 1 and 6.9 kbar).

tivity drop. The abrupt lattice expansion observed at T_C (Fig. 2) is attributed to the positive magnetovolume effect of the Co moment formation.

The metamagnetism is obviously absent in NdCo_2 in which the Co moment exists already in the paramagnetic range and just the ferromagnetic ordering of the Co and Nd moments takes place at T_C by a second-order magnetic phase transition. This is reflected in a change of slope of the $\rho(T)$ and $\Delta L/L(T)$ curves (see Figs. 3 and 4), respectively. Qualitatively comparable magnetovolume effects are observed at low temperatures both in Ho and Nd compounds, however.

Si substitutions for Co have a strikingly different impact on T_C in the two systems (see Figs. 1–4 and also Fig. 5). The slow decrease of T_C of Nd compounds with increasing x seems to reflect the dilution of a “magnetic” element (Co) by a “nonmagnetic” one (Si) but T_C increases rapidly in $\text{Ho}(\text{Co}_{1-x}\text{Si}_x)_2$ for x up to 0.075 followed by a slow decrease at a similar rate as for the Nd counterparts and the

FIG. 2. Temperature dependence of thermal expansion of $\text{Ho}(\text{Co}_{1-x}\text{Si}_x)_2$ for $x=0$ (in 1 and 4.7 kbar), 0.05 (in 1 and 5.5 kbar), and 0.075 (in 1 and 4.4 kbar).

FIG. 3. Temperature dependence of resistivity of $\text{Nd}(\text{Co}_{1-x}\text{Si}_x)_2$ for $x=0$ (in 1 and 5.6 kbar), 0.05 (in 1 and 2.4 kbar), and 0.075 (in 1 and 6.7 kbar).

relevant magnetization, resistivity, and volume anomalies associated with magnetic ordering become progressively broadened. Besides a more extended dilution of the Co sublattice, the effects of the increasing substitutional disorder on the Co sites on exchange interactions are considered as a possible source of this development. Note that the weak decreasing trend of the T_C vs x for the Nd system also becomes more pronounced for $x > 0.05$. The spin-reorientation temperature T_R is gradually lowered with increasing x both in the Nd and Ho systems.

The resistivity drop $\Delta\rho$ at T_C in $\text{Ho}(\text{Co}_{1-x}\text{Si}_x)_2$ is gradually reduced with increasing Si content and vanishes for $x > 0.075$. For $x \leq 0.05$, the resistivity decreases monotonously with further lowering temperature and tends to saturate in the low-temperature limit. For $x > 0.05$ the low-temperature behavior is modified and the resistivity increases with decreasing temperature. Discussion of this effect which

FIG. 4. Temperature dependence of thermal expansion of $\text{Nd}(\text{Co}_{1-x}\text{Si}_x)_2$ for $x=0$ (in 1 and 6.3 kbar), 0.05 (in 1 and 6.6 kbar) and 0.075 (in 1 and 5.7 kbar).

FIG. 5. Concentration dependence of T_C and T_R in $\text{Nd}(\text{Co}_{1-x}\text{Si}_x)_2$ (● and ▲) and $\text{Ho}(\text{Co}_{1-x}\text{Si}_x)_2$ (○ and △) for $x \leq 0.075$.

develops with further increasing x is beyond the scope of this paper. Similar effects were reported also for $\text{Er}(\text{Co}_{1-x}\text{Si}_x)_2$ (Ref. 14) and $\text{Ho}(\text{Co}_{1-x}\text{Al}_x)_2$ (Ref. 17) but are lacking in the $\text{Nd}(\text{Co}_{1-x}\text{Si}_x)_2$ compounds.

Magnetovolume data for $\text{Y}(\text{Co}_{1-x}\text{Al}_x)_2$ (Ref. 19) allow an assumption that the Co sublattice plays the dominant role in the magnetovolume phenomena in RECo_2 compounds. Then we may estimate the Co moment from the formula: $\omega_s \approx C\mu_{\text{Co}}^2$ (C is the magnetoelastic coupling constant). Ho compounds show an initial increase by about 10% for $x \leq 0.025$ followed by a monotonous decrease upon further increasing x . The Co expansion $\Delta V/V = 3\Delta L/L$ at T_C also vanishes for $x > 0.075$ where the Co metamagnetism disappears. The value of ω_s in $\text{Ho}(\text{Co}_{0.9}\text{Si}_{0.1})_2$ points to a considerable residual Co moment which, however, is not a result of any metamagnetism at T_C but may be tentatively attributed to a stable Co moment similar to NdCo_2 .

Application of pressure reduces T_C both in the Nd and Ho systems with almost composition invariant (for $x \leq 0.075$) values of $\partial \ln T_C / \partial p \approx -15$ and -23 Mbar^{-1} pointing to extrapolated critical pressures for the disappearance of ferromagnetism $p_c \approx 67$ and 43 kbar , respectively. The compressibility of the $\text{Ho}(\text{Co}_{1-x}\text{Si}_x)_2$ compounds which is $\kappa_p \approx 0.98 \text{ Mbar}^{-1}$ at room temperature increases drastically below T_C , where $\kappa_f = (\kappa_p + \kappa_m) = 1.4 \text{ Mbar}^{-1}$ for HoCo_2 , and κ_m is the magnetic contribution to the compressibility. This softening is intimately connected with the reduction of the spontaneous magnetostriction (see Fig. 2) due to pressure-induced suppression of the Co moment.

A rough estimation of the relevant softening of compressibility in the $\text{Nd}(\text{Co}_{1-x}\text{Si}_x)_2$ compounds gives a value, $\omega_s/p_c \approx 0.02 \text{ Mbar}^{-1}$, which is smaller by more than one order in comparison with the Ho compounds and well comparable with very small magnetostriction of all the ferromagnetic Co-rich alloys.

The results document that the Si substitutions for Co in the RECo_2 compounds are not only a simple dilution of the

Co sublattice, but besides the effective reduction of the overlap integral of $3d$ wave functions between Co-Co nearest neighbors (which may lead to a narrowing of the Co $3d$ band) and the variation of the count of Co $3d$ electrons in the system, a considerable involvement of the Si- $3p$ states in the electronic structure of the system has to be considered, namely their hybridization with the Co $3d$ states⁸ and the RE $5d$ states. The leading component of the exchange interaction coupling the RE magnetic moments and determining the ordering temperature in the heavy rare-earth RECo_2 materials without stable Co moments like in HoCo_2 is born from the hybridization of the RE $5d$ -electron states with the Co $3d$ states. The strong enhancement of the exchange interaction deduced from the increasing T_C in the heavy-rare-earth systems can be tentatively attributed to an additional contribution to the exchange interaction which arises from the $5d$ - $3p$ (Si) hybridization. In NdCo_2 and the other RECo_2 compounds with a stable Co magnetic moment the direct Co-Co ($3d$ - $3d$) exchange interaction also contributes substantially, acting as a leading term and yields considerably larger T_C values. Since the Co moment is instantly reduced with increasing Si content in the $\text{Nd}(\text{Co}_{1-x}\text{Si}_x)_2$ compounds, the Co-Co exchange interaction weakens reducing T_C as a direct consequence. The effects of the $3d(\text{Co})$ - $3p(\text{Si})$ hybridization involving both the Co moment and the exchange interaction within the Co sublattice cannot be omitted.

On the nature of the magnetic phase transition of the HoCo₂ intermetallic

P. J. von Ranke^{a)}

Ames Laboratory, Iowa State University, Ames, Iowa 50011

N. A. de Oliveira^{b)}

Universidade do Estado do Rio de Janeiro, Rua São Francisco Xavier 524, Rio de Janeiro, RJ 20550-013, Brazil

In this work we calculate the itinerant and localized magnetization curves of the Laves phase intermetallic compound HoCo₂ and discuss the nature of its magnetic phase transition. The numerical results were calculated from the self-consistent solution of magnetic coupled equations obtained through the combination of functional integral methods with molecular field approximation. © 1998 American Institute of Physics. [S0021-8979(98)24711-6]

An interesting feature presented by rare-earth cobalt intermetallic compounds RCo₂ (R=Er, Dy, Ho), is the existence of a first-order magnetic phase transition,¹⁻⁹ which has been discussed in the literature in terms of the instability of the Landau free energy around the critical temperature.³ However, as far as we know, there are no explicit calculations of the effects of the temperature on the magnetization curve of these intermetallics. This kind of calculation is very important, not only to determine the order of the magnetic phase transition but also to determine the possible change of easy magnetization direction and to find any anomalies along the magnetization curve.

The main goal of this article is to calculate in a quantitative way the temperature dependence of the itinerant and localized parts of the magnetization of the Laves phase intermetallic compound HoCo₂ and to discuss the nature of its magnetic phase transition. In the formulation of the problem we start from the following two-sublattice model Hamiltonian including localized spins and itinerant electrons, in the approximation of five identical *d* subbands:¹⁰

$$H = \sum_l \epsilon_0^{\text{Ho}} a_{l\sigma}^+ a_{l\sigma} + \sum_{ll'} T_{ll'}^{\text{HoHo}} a_{l\sigma}^+ a_{l'\sigma} + \sum_j \epsilon_0^{\text{Co}} a_{j\sigma}^+ a_{j\sigma} + \sum_{jj'} T_{jj'}^{\text{CoCo}} a_{j\sigma}^+ a_{j'\sigma} + \sum_{lj} T_{lj}^{\text{HoCo}} (a_{l\sigma}^+ a_{j\sigma} + a_{j\sigma}^+ a_{l\sigma}) + U^{\text{Ho}} \sum_l n_{l\uparrow} n_{l\downarrow} + U^{\text{Co}} \sum_j n_{j\uparrow} n_{j\downarrow} - J_{df} \sum_l J_l^f S_l^d. \quad (1)$$

Here ϵ_0^{Ho} is the center of *d*-energy band at Ho sublattice; ϵ_0^{Co} is the corresponding term of the Co sublattice; the terms $T_{ll'}^{\text{HoHo}}$ and $T_{jj'}^{\text{CoCo}}$ represent the hopping between sites of the same sublattice, and T_{lj}^{HoCo} is the intersublattice hopping. U^{Ho} (U^{Co}) is the Coulomb interaction parameter between itinerant electrons at Ho (Co) site; J_{df} is the exchange integral interaction parameter between localized 4*f* spins and itinerant electrons and J^f is the total angular momentum of Ho⁺³ ions.

Using the functional integral method in the static approximation to treat the electron-electron interaction,¹⁰ we decouple the total Hamiltonian (1) into two new effective ones:

$$\bar{H}_f = -J_{df} \sum_l \langle S_l^d \rangle \cdot J_l^f - \sum_{ll'} J_l^f \left[\frac{1}{2} \left(\frac{J_{df}}{g_e \mu_B} \right)^2 \cdot \chi_{ll'}^d \right] \cdot J_{l'}^f, \quad (2)$$

$$\begin{aligned} \bar{H}_d = & \sum_l \epsilon_{l\sigma}^{\text{Ho}} a_{l\sigma}^+ a_{l\sigma} + \sum_{ll'} T_{ll'}^{\text{HoHo}} a_{l\sigma}^+ a_{l'\sigma} + \sum_j \epsilon_{j\sigma}^{\text{Co}} a_{j\sigma}^+ a_{j\sigma} \\ & + \sum_{jj'} T_{jj'}^{\text{CoCo}} a_{j\sigma}^+ a_{j'\sigma} + \sum_{lj} T_{lj}^{\text{HoCo}} (a_{l\sigma}^+ a_{j\sigma} + a_{j\sigma}^+ a_{l\sigma}) \\ & - J_{df} \sum_l J_l^f S_l^d, \end{aligned} \quad (3)$$

where μ_B is the Bohr magneton and g_e is the Landé factor of the itinerant electrons. The effective Hamiltonian (\bar{H}_f) de-

FIG. 1. Temperature dependence of the itinerant (M^{Co}) and localized (M^{Ho}) magnetization of HoCo₂ (in units of μ_B). The full lines are the theoretical calculations and the circles (squares) are experimental data for Ho (Co) (see Ref. 9).

scribes a subsystem of the localized $4f$ spins coupled to itinerant electrons via the itinerant magnetization $\langle s_l^d \rangle$ and via the electronic magnetic susceptibility $\chi_{ll'}^d$. The term in brackets in (\bar{H}_f) , which depends on the magnetic susceptibility of itinerant electrons, defines an effective exchange interaction between localized $4f$ spins.¹⁰ This effective exchange interaction establishes a connection between the localized magnetization at Ho sites and the electronic structure of the Co sublattice and plays an important role in the appearance of local magnetization at Ho sublattice. Using the molecular field approximation, the temperature dependence of localized magnetization (M^{Ho}) of the Ho sublattice, is obtained in a standard way in terms of Brillouin function.

$$M^{\text{Co}} = \langle \xi \rangle = \frac{\int d\xi d\nu \xi e^{-\beta\{U^{\text{Co}}/4(\xi^2 + \nu^2) + 1/\pi \int dz f(z) \text{Im} \sum_{\sigma} \ln[1 - V^{\text{Co}}(\xi\nu) F_{\sigma}^{\text{Co}}(z)]\}}}{\int d\xi d\nu e^{-\beta\{U^{\text{Co}}/4(\xi^2 + \nu^2) + 1/\pi \int dz f(z) \text{Im} \sum_{\sigma} \ln[1 - V^{\text{Co}}(\xi\nu) F_{\sigma}^{\text{Co}}(z)]\}}}, \quad (4)$$

where $f(z)$ is the Fermi function; $z = \epsilon + i\delta$, $\delta \rightarrow 0$; V^{Co} is a local potential at the Co sublattice that comes from the CPA treatment of the disordered Hamiltonian and F^{Co} is the local Green's function of the Co sublattice.¹⁰

The magnetization curve of the HoCo_2 intermetallic was calculated using a standard model d density of states extracted from *ab initio* calculation¹¹ and the following fixed parameters: $U^{\text{Ho}} = 0.5$ eV, $U^{\text{Co}} = 1.0$ eV, and $J_{df} = 0.065$ eV. The calculated temperature dependence of the itinerant and localized magnetizations of the HoCo_2 intermetallic, Fig. 1, shows a first-order magnetic phase transition at $T_c = 80$ K. In this intermetallic, the first-order magnetic phase transition is associated with the abrupt enhancement of the effective exchange interaction between localized spins near the critical temperature. This abrupt enhancement can be explained in the following way: due to the position of the Fermi level in a deep region near a sharp peak in the d density of states, a small value of the localized magnetization at the rare-earth sublattice induces a metamagnetic transition at the Co sublattice, yielding an abrupt enhancement of the electronic magnetic susceptibility and consequently in the effective exchange interaction parameter between localized spins. This self-consistent process gives rise to a large value of the magnetic moment at Ho sites, thus producing a discontinuity in the magnetization curve at the critical temperature.

This model can be straightforwardly extended to calculate the temperature and concentration dependence of the magnetization of $\text{R}(\text{Co}_{1-x}\text{T}_x)_2$ pseudobinaries,^{12,13} where (R=Er, Dy, Ho) and T is sp or d -transition element. In

The effective Hamiltonian (\bar{H}_d) describes a two-sublattice itinerant electron system without electron-electron interaction and under the action of an effective magnetic field generated by the localized $4f$ spins. In this Hamiltonian the effective energies $\epsilon_{l\sigma}^{\text{Ho}}$ and $\epsilon_{j\sigma}^{\text{Co}}$ incorporate fluctuating charge (ν) and spin (ξ) fields defining a very complicated disorder problem. In order to simplify the numerical calculations, we use the homothetic band approach to treat the two sublattices of the intermetallic and use the coherent potential approximation (CPA) to deal with the intrinsic disorder introduced by the functional integral method.¹⁰ Within these approximations, the temperature dependence of the itinerant magnetization on the Co sublattice (M^{Co}) is given self-consistently by the mean value of the spin fluctuating field:¹⁰

these pseudobinaries, increasing T concentration smears out the electronic density of states near the Fermi level in a such way that the effective exchange interaction parameter between localized spins increases smoothly with temperature, changing the nature of the magnetic phase transition from first to second order.

The authors are greatly indebted with Professor Affonso Gomes for his help in the development of the theoretical formulation presented in this article. This work was partially supported by CNPq (Brazilian agency of funds).

Recovery of ErCo₂ Fermi level by substitution of Co by Ni and Fe

F. Garcia,^{a)} H. dos Santos, M. R. Soares, A. Y. Takeuchi, and S. F. da Cunha

Centro Brasileiro de Pesquisas Físicas, 22290-180, Rio de Janeiro, Brazil

Magnetic and electrical resistivity measurements performed in Er(Co_{1-x}Ni_x)₂ have shown that the critical concentration for the first-order magnetic phase transition is near to $x_c = 0.10$. For higher Ni concentration the results suggest that Co is no longer magnetic. Experimental results presented here for Er(Co_{0.8}Ni_{0.2x}Fe_{0.2(1-x)})₂ and Er(Co_{0.9}Ni_{0.1x}Fe_{0.1(1-x)})₂ systems, show that when Co is replaced by Fe, the 3d band is filled up, whereas for Ni substitution that band is depleted. The saturation moment obtained from isothermal magnetization measurements indicates that Co recovers its moment and couples parallel to the Fe moment and antiparallel to the Er moment. Characteristics of spin fluctuation are also observed. These results show that with a suitable combination of Co, Ni, and Fe we can recover the original density of the states of the ErCo₂ compound. © 1998 American Institute of Physics. [S0021-8979(98)24811-0]

I. INTRODUCTION

Within the series of R-3d (R=heavy rare earth) intermetallics the RCo₂ Laves phases show interesting magnetic properties.¹ In contrast to RFe₂, where the Fe moments are practically independent, whether the R ions bear a magnetic moment or not, the existence of a Co moment is intimately connected with the existence of a moment on the R sites. On the other hand, in RNi₂, where the Fermi-level E_F lies in the flat low density of states $N(E)$ region, Ni is never magnetic in this system, even in compounds with magnetic R ions. From band-structure calculations² it has been concluded that most of the outstanding features observed in the family of the RCo₂ compounds can, at least qualitatively, be understood by considering the Fermi-level position E_F , which is situated near a local peak. The high value together with a special shape of the density of states $N(E)$ curves in the vicinity of the Fermi level give rise to spin fluctuations in the d band and they are also responsible for the occurrence of itinerant metamagnetism.

In the present work, electrical resistivity and magnetization measurements in some selected samples of Er(Co, M)₂ (M=Fe and Ni) compounds were performed in order to get further information to support the band picture for the observed behaviors. A small amount of Co is replaced by 3d transition metals Fe and Ni in ErCo₂. As Fe substitution shifts the Fermi level toward lower energy, while Ni substitution shifts it toward higher energy, we might obtain the characteristic of the original density of states of the ErCo₂ compound by suitable combination of Co, Ni, and Fe.

II. EXPERIMENTAL PROCEDURE

The samples were prepared by arc melting the constituent elements in an argon atmosphere. To avoid the appearance of spurious phases, a 6 wt % excess of rare earth over the stoichiometric composition was necessary. The ingots were then annealed in evacuated sealed quartz tubes for a period of one week at $T = 800^\circ\text{C}$. The crystal structure and

the lattice parameter were determined at room temperature by x-ray powder diffraction. All the samples are single phase cubic MgCu₂ type.

Electrical resistivity measurements were performed using a standard dc four-point method; magnetization measurements were carried out using a vibrating sample magnetometer and magnetic ac susceptibility (χ_{AC}) measurements were performed using a lock-in amplifier ($f = 125\text{ Hz}$).

III. RESULTS AND DISCUSSION

The temperature dependence of the magnetization (in $H_{app} = 100\text{ Oe}$) in all samples shows a difference between field-cooled and zero-field-cooled measurements, for $T < T_C$. This difference disappears under higher applied fields (5 kOe). This thermal irreversibility is related to domain-wall motion in the crystal. The saturation moments per formula unit μ_{sat}/fu of these compounds were obtained by extrapolation of the magnetization to infinite field, from M vs $1/H$ curves performed at 4.2 K, in fields up to 80 kOe.

Figure 1 shows the electrical resistivity ρ versus temperature of the Er(Co, M)₂ (M=Fe, Ni) system. The residual resistivity has been subtracted in these plots. The $\rho(T)$ curves for ErCo₂ and Er(Co_{0.90}Ni_{0.10})₂ (Ref. 3) show a discontinuous change at T_C , characteristic of a first-order transition. At high temperatures (basically, $T > T_C$) these curves present a clear tendency towards saturation and huge values, if compared to the De Gennes–Friedel spin-disorder resistivity. This additional contribution to the resistivity was well explained by Baranov *et al.*⁴ as spin-fluctuation scattering of the 3d band.

For Er(Co_{0.80}Ni_{0.20})₂, apart from the peak at low temperatures, the temperature dependence of the electrical resistivity $\rho(T)$ is typically of metallic ferromagnets (see ErNi₂) and shows an anomaly at $T = T_C$. The pronounced curvature of $\rho(T)$ curves (characteristic for the spin-fluctuation system) that is observed in ErCo₂ above T_C is suppressed for more than 20 at. % Ni and the temperature dependence becomes almost constant. On the other hand, the saturation moments per formula unit μ_{sat}/fu for ErNi₂ and Er(Co_{0.80}Ni_{0.20})₂ compounds are $7.2\mu_B$ and $7.1\mu_B$, respec-

^{a)}Electronic mail: flavio@cat.cbpf.br

FIG. 1. Temperature dependence of the electrical resistivity for $\text{Er}(\text{Co}, \text{M})_2$ ($\text{M}=\text{Fe}$ and Ni).

tively. These properties suggest that in alloys containing more than about 20 at. % Ni, the Co is no longer magnetic.

Bearing in mind that the main purpose of this work is to recover the original ErCo_2 Fermi-level position, we performed measurements in $\text{Er}(\text{Co}_{0.80}\text{Fe}_{0.14}\text{Ni}_{0.06})_2$ and $\text{Er}(\text{Co}_{0.80}\text{Fe}_{0.13}\text{Ni}_{0.07})_2$ compounds. Indeed, results of $\rho(T)$ curves show behavior similar to that of ErCo_2 , i.e., saturation tendency above T_C indicating that spin-fluctuation scattering is present. As the spin-fluctuation scattering produces an additional contribution to the electrical resistivity at high tem-

peratures, we estimated the total variation of the resistivity $\Delta\rho = \rho(300\text{ K}) - \rho(1.5\text{ K})$. For ErCo_2 we found $\Delta\rho = 121\text{ }\mu\Omega\text{ cm}$ and for ErNi_2 and $\text{Er}(\text{Co}_{0.80}\text{Ni}_{0.20})_2$, 37 and $40\text{ }\mu\Omega\text{ cm}$, respectively. However, in $\text{Er}(\text{Co}_{0.80}\text{Fe}_{0.13}\text{Ni}_{0.07})_2$ and $\text{Er}(\text{Co}_{0.80}\text{Fe}_{0.14}\text{Ni}_{0.06})_2$, $\Delta\rho$ reaches values of 94 and $135\text{ }\mu\Omega\text{ cm}$, respectively. These results show clearly that spin-fluctuation effects are present in these compounds.

Around T_C , the resistivity curves show a sharp increase. However, they are not a conclusive indication of a first-order transition.⁵ To try to elucidate this point we have measured a sample of $\text{Er}(\text{Co}_{0.90}\text{Fe}_{0.07}\text{Ni}_{0.03})_2$. Results show a larger variation of ρ at T_C , but it is not yet conclusive about the order of the phase transition, in contrast to the situation for $\text{Er}(\text{Co}_{0.90}\text{Ni}_{0.10})_2$,³ which presents a clearly first-order phase transition. This behavior is not unexpected, considering that there is a large chemical disorder (Fe, Co, and Ni) in the crystal. This disorder can produce a distribution of first-order transition phase temperatures.

IV. CONCLUSIONS

We have successfully reproduced in substituted compounds the Fermi level of ErCo_2 . This conclusion is of use in theoretical models where parameters largely depend on the detailed form of the band structure. Moreover, the electrical resistivity results are also important to a better understanding of the saturation and spin-fluctuations effects. The first-order transition cannot be clearly confirmed, but there is a strong indication of its presence.

We theoretically discuss the local moment formation and the hyperfine field behavior of nonmagnetic ($s-p$ and noble) impurities diluted in ferromagnetic rare-earth compounds GdX (X=Zn, Cd). It is experimentally observed in these systems that all impurities enter substitutionally at the "nonmagnetic" X lattice site, creating a strong local charge perturbation. In our simplified model, one calculates the local magnetic moment in the perturbed conduction band at the origin (a charge perturbed X site). The polarization of the conduction band arises from the Gd 4f moments and the conduction electron polarization produced by the host magnetic moment at the origin is treated within the Born approximation. The general trend of the experimental hyperfine field data is well reproduced by our self-consistent calculations. © 1998 American Institute of Physics. [S0021-8979(98)40111-7]

In recent years, a systematic experimental study was made in order to obtain the magnetic hyperfine field at nonmagnetic ($s-p$ and noble) impurities diluted in the intermetallic compounds GdZn and GdCd.¹ These compounds have the CsCl type structure with lattice parameter $a=3.60$ and 3.75 Å and are ferromagnetic below $T_c=270$ and 265 K, respectively. The saturation magnetic moment of GdZn is $7.50\mu_B$, the excess moment of $0.5\mu_B$ being ascribed to $5d$ conduction electrons. Similarly, one has an excess moment of about $0.4\mu_B$ in the case of GdCd. The hyperfine field at an impurity in GdZn was found to be nearly the same to that in GdCd; moreover, the experimental data showed that the behavior of the hyperfine fields at nonmagnetic impurities in GdX (X=Zn, Cd) are quite similar to those in Gd metal, i.e., one always has negative hyperfine fields along a $s-p$ series.

As far as ferromagnetic Gd host is concerned, the experimental results can be compared with the calculation of Leal *et al.*,² which is an extension of the Daniel-Friedel model.³ More recently, de Oliveira *et al.*⁴ have discussed the problem of nonmagnetic impurities in Gd and Ni hosts, using a formulation due to Speier *et al.*,⁵ which takes into account neighbor effects arising from the translational symmetry breaking. The model described in Ref. 4 was also used to describe intermetallic compounds GdX (X=Zn, Cd).⁶ In that work, an effective one-site host model was adopted, where the intermetallic compound was described by a single lattice constituted by the same "effective atoms," namely Gd-like elements, which create a host exchange splitting proportional to the excess of magnetization verified in the GdX (X=Zn, Cd) compounds. A weakness of the model⁶ is that it is experimentally known that the nonmagnetic impurities enter at the X site.¹ Moreover, the polarization of the conduction

electron gas is created by the Gd 4f spins, located at the Gd sublattice sites which interact with the $5d$ -conduction electrons of the compound, thus originating also the indirect interaction between the Gd moments.

In order to partially restore the two sublattice character of the GdX compounds, we would like to discuss here a theoretical approach to study the systematics of hyperfine fields at nonmagnetic impurities placed in GdZn and GdCd compounds. This approach is based on a two-center model introduced by Blandin and Campbell⁷ to discuss hyperfine fields at $s-p$ sites (Y) in Heusler alloys X_2MnY . We hope to bring out in this formulation the effect of charge screening at the nonmagnetic impurity site, on the polarization at that site. In this sense, our present calculation can be seen as an extension of the Ruderman-Kittel-Kasuya-Yosida (RKKY) approach to an electron gas with a strong local charge perturbation.

The unperturbed conduction electrons within a tight binding formulation are described by the propagator:

$$g_{ij}(E) = \sum_k \frac{e^{i\mathbf{k} \cdot (\mathbf{R}_i - \mathbf{R}_j)}}{E - \epsilon_k}, \quad (1)$$

where ϵ_k is the dispersion relation for the conduction band.

A nonmagnetic impurity at the origin introduces a spin-independent local potential V_0 , originated from the charge difference between impurity and host conduction electrons. The spin-dependent potential, introduced by a polarized 4f spin located at \mathbf{R}_n is given by $V_n^\sigma = \sigma J \langle S_Z \rangle$. So, the general Dyson equation defining the two-center scattering problem is

$$G_{ij}^\sigma(E) = g_{ij}(E) + \sum_{l,m} g_{il}(E) V_{lm}^\sigma G_{mj}^\sigma(E), \quad (2)$$

with

$$V_{lm}^{\sigma} = V_0 \delta_{lm} + V_n^{\sigma} \delta_{lm} \delta_{mn}. \quad (3)$$

In order to get the spin polarization at the origin, let us define

$$G_{ij}^{\sigma}(E) = g_{ij}(E) + \delta G_{ij}^{\sigma}(E). \quad (4)$$

The *exact* solution of the scattering problem defined by (2)–(4) leads to

$$\begin{aligned} \delta G_{00}^{\sigma}(E; \mathbf{R}_n) &= \frac{g_{0n}(E)g_{n0}(E)}{[1 - V_0 g_{00}(E)]^2} \\ &\times \left\{ \frac{V_n^{\sigma}}{1 - V_n^{\sigma} [g_{00}(E) + g_{n0}(E)T_0(E)g_{0n}(E)]} \right\} \end{aligned} \quad (5)$$

and therefore

$$\begin{aligned} \sum_{\sigma} \sigma \delta G_{00}^{\sigma}(E; \mathbf{R}_n) &= \frac{2J\langle S_Z \rangle g_{0n}(E)g_{n0}(E)}{[1 - V_0 g_{00}(E)]^2} \\ &\times \left\{ \frac{1}{1 - J\langle S_Z \rangle [g_{00}(E) + g_{n0}(E)T_0(E)g_{0n}(E)]} \right\}, \end{aligned} \quad (6)$$

with

$$T_0(E) = \frac{V_0}{1 - V_0 g_{00}(E)}. \quad (7)$$

The spin-dependent potential V_n^{σ} is small as compared to the strong local charge potential perturbation V_0 ; so it can be treated in the Born approximation, yielding:

$$\begin{aligned} \delta G_{00}^{\uparrow}(E; \mathbf{R}_n) - \delta G_{00}^{\downarrow}(E; \mathbf{R}_n) &= \frac{2J\langle S_Z \rangle}{[1 - V_0 g_{00}(E)]^2} g_{0n}(E)g_{n0}(E) + \mathcal{O}(J\langle S_Z \rangle)^3. \end{aligned} \quad (8)$$

Since we are interested in the hyperfine field at the origin, we calculate the local magnetization $\tilde{m}(0)$ arising from the *sum* of contributions over neighboring magnetic sites. So

$$\begin{aligned} \tilde{m}(0) &= -\frac{1}{\pi} \int_{-\infty}^{E_F} \text{Im} \frac{2J\langle S_Z \rangle}{[1 - V_0 g_{00}(E)]^2} \\ &\times \sum_n g_{0n}(E)g_{n0}(E) dE \\ &= \frac{1}{\pi} \int_{-\infty}^{E_F} \frac{2J\langle S_Z \rangle}{[1 - V_0 g_{00}(E)]^2} \left[Z \frac{\partial g_{00}(E)}{\partial E} \right. \\ &\quad \left. + g_{00}^2(E) \right] dE, \end{aligned} \quad (9)$$

where Z represents the number of neighboring magnetic impurities. In the present case, each X site is surrounded by 8 Gd neighbors and therefore $Z=8$.

Notice that if one introduces the effect of a nonlocal charge potential due to the impurity symmetry breaking, it is

FIG. 1. Calculated hyperfine fields for 4s-p impurities in GdZn (full line) and GdCd (dashed line) compounds. The experimental data (squares for GdZn and open circles for GdCd) were collected from Ref. 1.

easily shown that at the lowest approximation the local potential V_0 can be replaced by the effective nonlocal potential^{4,5}

$$V_{\text{eff}} = V_0 + (\alpha^2 - 1)E, \quad (10)$$

where α is a proportionality factor associated to the radii of the impurity and host atomic wave functions and V_{eff} is self-consistently obtained via an extended Friedel sum rule.⁸ Then, one obtains the conduction electron polarization (CEP) hyperfine field

$$H_{\text{hf}} = A(Z_{\text{imp}})\tilde{m}(0), \quad (11)$$

where $A(Z_{\text{imp}})$ is the Fermi–Segrè coupling estimated by Campbell.⁹ In our self-consistent numerical calculations, we adopted a density of states similar to that calculated by Postnikov *et al.*¹⁰ Figure 1 illustrates the self-consistently calculated CEP hyperfine field at 4s-p impurities in GdX intermetallics. In Fig. 2 the case of 5s-p impurities is exhibited

FIG. 2. Calculated hyperfine fields for 5s-p impurities in GdZn (full line) and GdCd (dashed line) compounds. The experimental data (squares for GdZn and open circles for GdCd) were collected from Ref. 1.

and one observes a quite similar behavior, i.e., all hyperfine fields are negative and the corresponding negative local moments are very small. Similarly to our previous Daniel–Friedel type calculation,⁶ discrepancies are systematically observed in the case of isoelectronic noble impurities Cu, Ag, and Au. This is because the impurity nd^{10} filled shell creates at the strongly charge perturbed local density of states at the origin, an Anderson–Moriya d -hump.¹¹ The Friedel–Anderson-like d resonance generates a local d moment, which turns out to be of the order of $0.25\mu_B$, thereby originating a core polarization contribution to the hyperfine field. Full details about this calculation will be given elsewhere.¹²

In this article we report a new compound, $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$, which behaves like SmMn_2Ge_2 , a compound with reentrant ferromagnetic order. Magnetization and thermal expansion measurements have been performed to study polycrystalline $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$. Temperature dependent magnetization data shows that from 800 to 426 K the sample behaves like a paramagnet. A Néel transition is observed at 426 K (T_4) and the antiferromagnetic phase persists until 334 K (T_3). From 334 K (T_3) to 277 K (T_2) the sample exists in a ferromagnetic state. At 277 K (T_2) the sample transforms into an antiferromagnetic phase. Interestingly, at 117 K (T_1) the sample enters into a ferromagnetic-like phase. Thermal expansion study shows a sharp change in the sample dimension around T_1 (125 K). This change in the dimension most likely triggers the reentrant magnetic transition (T_1) observed in the magnetization measurement. The sharp change in thermal expansion suggests this transition at T_1 to be of first order. The relatively small and shallow dimensional change around T_2 (275 K) implies a weak first order transition. The dimensional changes found at the two transitions strongly suggest that Mn–Mn intralayer distance plays an important role in the multiple magnetic phases in $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$. © 1998 American Institute of Physics.

The rare-earth-intermetallic compounds RMn_2X_2 (R =rare-earth, X =Ge, Si) have been studied^{1,2} intensively for more than 15 years. The various compounds with different R and X combinations show a wide variety of magnetic behavior. All the RMn_2X_2 compounds have tetragonal ThCr_2Si_2 crystal structure, where each element resides in a square plane of their own and these planes are then stacked along the c axis with the sequence ... $\text{R}-\text{X}-\text{Mn}-\text{Mn}-\text{X}-\text{R}$... the easy axis of magnetization being along the c axis.

Among all the RMn_2X_2 compounds, SmMn_2Ge_2 possesses the most intriguing magnetic behavior.³ With the lowering of temperature from 400 to 2 K it shows four distinct magnetic states: from 400 to ~ 340 K (T_3) it is paramagnetic; from 340 to ~ 150 K (T_2) it is ferromagnetic; from 150 to ~ 100 K (T_1) it is antiferromagnetic; and finally, it reenters another ferromagnetic phase below 100 K and this is sustained until 2 K, the lowest temperature of measurement. Temperature dependence of lattice constants⁴ shows that the ferro- to antiferromagnetic (T_2) and antiferromagnetic to ferromagnetic (T_1) transitions are enhanced by magnetostriction. More importantly, these interesting transitions in SmMn_2Ge_2 and also the magnetic behavior of the whole family of RMn_2X_2 compounds is strongly correlated to the Mn–Mn intralayer distance $R_{\text{Mn}-\text{Mn}}^a$.^{3–5} This critical dependence has been investigated in RMn_2Ge_2 and in particular in SmMn_2Ge_2 by external pressure^{6,7} and by chemical pressure.^{8–10} NMR study¹¹ has been done on SmMn_2Ge_2 to understand reentrant ferromagnetism. A magnetoresistance study¹² on SmMn_2Ge_2 indicates a new transition around 30 K and it has been attributed to Sm.

Due to very high neutron absorption coefficient of Sm, it has not been possible to subject SmMn_2Ge_2 to neutron dif-

fraction experiments. Therefore, the suggestions on the magnetic structure of SmMn_2Ge_2 were largely made on the basis of the pressure and temperature-dependent magnetization studies of SmMn_2Ge_2 and those of the other members of the RMn_2X_2 compounds.^{3,4,7} It was thought that magnetic moments of Mn are always arranged parallel (giving ferromagnetic order) within the (001) plane and depending on temperature the moments on two successive planes could be either directed parallel or antiparallel. This view has recently been revised¹³ due to the understanding of the Mn-sublattice ordering from the neutron diffraction studies on RMn_2Ge_2 (La–Nd), LaMn_2Si_2 , and $\text{La}_{0.3}\text{Y}_{0.7}\text{Mn}_2\text{Ge}_2$ compounds.^{14–16} According to these studies, the Mn moments in many RMn_2X_2 compounds possess both ferromagnetic and antiferromagnetic components giving a canted arrangement. Having found the magnetic structure of RMn_2X_2 compounds, Venturini *et al.*¹³ synthesized a SmMn_2Ge_2 -like compound, $\text{Nd}_{0.35}\text{La}_{0.65}\text{Mn}_2\text{Si}_2$, and they have studied it by magnetization and neutron diffraction measurements. The magnetic structure found for $\text{Nd}_{0.35}\text{La}_{0.65}\text{Mn}_2\text{Si}_2$ is thought to be valid for SmMn_2Ge_2 . In this article we report on a new compound, $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$, which also shows SmMn_2Ge_2 -like behavior. This compound can provide us understanding of the reentrant magnetic behavior in SmMn_2Ge_2 and in other similar compounds.

Samples were synthesized by arc melting in Ar atmosphere of the proper amounts of the constituent elements. The purity of the elements were 99.9% for Tb and Nd, 99.99% for Mn, and 99.999% for Ge. Samples were then annealed under vacuum at 1173 K for ten days. Magnetization measurements were carried out by means of a SQUID magnetometer. The magnetization measurements above 400

FIG. 1. High-temperature magnetization data of the $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$ sample at an applied field of 500 G. The inset shows inverse magnetization as a function of temperature.

K were carried out with a vibrating sample magnetometer. Thermal expansion measurements were made by using a capacitance dilatometer. X-ray data reflect the presence of a main phase with ThCr_2Si_2 -type tetragonal structure. It also shows the presence of a minor amount of impurity phase.

Figure 1 shows the high-temperature magnetization of $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$ at a constant applied field of 500 G. From 800 K down to about 470 K the inverse magnetization (inset) shows a good linear dependence on temperature indicating that the moments are paramagnetic. The cusp at 426 K (T_4) indicates a Néel transition and the antiferromagnetic phase (AFI) persists down to 335 K (T_3). It is important to note that in $\text{Nd}_x\text{Tb}_{1-x}\text{Mn}_2\text{Ge}_2$ compound⁸ the Néel transition was not observed. A comparison between the magnetic orderings of the Mn moments in TbMn_2Ge_2 (Ref. 17) [where Mn mo-

FIG. 2. Temperature dependence of magnetization of $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$ at different magnetic fields ranging from 500 G to 10 kG. The inset shows a magnified view of the magnetization vs temperature data at 500 G.

FIG. 3. (a) Magnetization of $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$ as a function of applied magnetic field at different temperatures. (b) Magnetic hysteresis curve of $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$ at 5 K.

ments are arranged ferromagnetically along the (001) planes] and in NdMn_2Ge_2 (Ref. 13) [where Mn moments have both ferromagnetic and antiferromagnetic components along the (001) planes] suggest that Mn moments might have an antiferromagnetic ordering in $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$ in the temperature range of 426 to 335 K. However, further investigation in this temperature range is necessary for a definitive conclusion. Figure 1 also shows that the sample is transformed into a ferromagnetic phase (FMI) below 335 K. Inset of Fig. 2 shows the temperature-dependent magnetization data of the $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$ sample at temperatures below 400 K and at a constant applied field of 500 G. Below 335 K the sample is transformed into a ferromagnetic phase (FMI). This ferromagnetic ordering most likely is coming from the ferromagnetic coupling among the Mn moments in the adjacent Mn planes.¹³ This ferromagnetic phase is retained down to 277 K (T_2) where the sample transforms to an antiferromagnetic phase (AFII). The AFII phase extends down to 117 K (T_1). As the temperature is decreased further, the sample transforms into the apparent ferromagnetic phase. The magnetization data in the inset of Fig. 2 thus suggests that $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$ behaves very similar to SmMn_2Ge_2 . The low-temperature magnetic ordering in $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$ is most likely due to the ordering of Tb and Nd moments as well as Mn moments. To better understand the magnetic behavior of the sample, especially below 100 K, we performed several temperature-dependent measurements at different magnetic fields. This result is shown in Fig. 2. The data

FIG. 4. Relative thermal expansivity $\Delta l/l$ of $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$ as a function of temperature.

below 50 K for 1 kG field show that the sample approaches the saturation value. Surprisingly, this indication of saturation reverses for high field measurements at 5 and 10 kG. This may suggest that the rare-earth sublattice in $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$ has a complicated magnetic structure due to the competition between the Tb–Mn, Nd–Mn, and Tb–Nd couplings. This complicated magnetic behavior is also indicated from the neutron study⁸ on the two closest compounds, namely, $\text{Tb}_{0.6}\text{Nd}_{0.4}\text{Mn}_2\text{Ge}_2$ and $\text{Tb}_{0.8}\text{Nd}_{0.2}\text{Mn}_2\text{Ge}_2$. At low temperature $\text{Tb}_{0.8}\text{Nd}_{0.2}\text{Mn}_2\text{Ge}_2$ shows a ferrimagnetic structure of the Mn and R magnetic moments along the *c* axis. On the other hand, at low temperature $\text{Tb}_{0.6}\text{Nd}_{0.4}\text{Mn}_2\text{Ge}_2$ has a ferromagnetic component along the *c* axis and an antiferromagnetic one along the *a* axis.

Figure 3(a) shows isothermal magnetization data with the variation of applied field. At 50 K magnetization increases relatively faster at low fields (up to 5 kG) and increases with the increase of the field but never saturates, even at 55 kG, the maximum applied field. At 5 K magnetization increases slowly up to 7.5 kG. The curvature becomes positive for fields higher than 7.5 kG. Again, at 5 K magnetization does not saturate at 55 kG. The steady increase in the magnetization for high fields at 50 and 5 K indicates that at low temperatures there may be an antiferromagnetic component present in the magnetic ordering of the rare-earth elements in $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$ and the overall magnetic ordering is not simple collinear ferromagnetic or ferrimagnetic. Figure 3(b) shows the magnetic hysteresis curve of $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$ at 5 K. The hysteresis, with rather high coercivity, at least shows that at low temperature $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$ has either ferromagnetic or ferrimagnetic order in it.

In RMn_2Ge_2 compounds, especially in SmMn_2Ge_2 , the FM–AF and AF–FM transitions accompany magnetostric-

tion. To verify any possible dimensional change in the $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$, we measured its relative thermal expansivity from 5 K to room temperature. This result is presented in Fig. 4. At 120 K a sharp change in the sample dimension occurs. This transition temperature corresponds to the reentrant magnetic transition (T_1) found in the magnetization measurement (inset of Fig. 2). The sharp dimensional change clearly indicates that the order of the transition is of first order. Thermal expansion data also indicate a small and shallow dimensional change around 275 K. This dimensional change corresponds to the AFI–FMI transition (T_2) observed in the magnetization measurement. Considering the magnetization and thermal expansion data we suggest this transition at T_2 to be of weak first-order type. The dimensional change observed at T_1 and T_2 strongly suggest that Mn–Mn intralayer distance plays an important role in the magnetic behavior of $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$.

A neutron diffraction study would be necessary to determine the magnetic structure of $\text{Tb}_{0.7}\text{Nd}_{0.3}\text{Mn}_2\text{Ge}_2$ and it would provide a more complete understanding of the magnetic behavior of this as well as other compounds with reentrant magnetic behavior.

Max-Planck-Institut für Festkörperforschung, Heisenbergstr. 1, D-70569 Stuttgart, Germany

The antiferromagnetic $\text{BaCo}_{0.9}\text{Ni}_{0.1}\text{S}_{2-y}$ and the paramagnetic CuIr_2S_4 Mott systems show an inverse conductivity behavior, i.e., the metallic phase occurs at low or high temperatures, respectively, which also suggests inverse behavior in other transport properties. In this contribution we present magnetization data, conductivity, thermal conductivity, and Seebeck effect in the temperature range $4.2 \text{ K} < T < 350 \text{ K}$ and in particular through the metal-insulator transition at T_{MI} . We recover the anomalies in $\chi(T)$, $\sigma(T)$, which are discussed using Jahn-Teller and anti-Jahn-Teller models; also, we compare the anomalies in $\sigma(T)$, $S(T)$, and of the heat conductivity $\kappa(T)$ at T_{MI} . In particular, for $\text{BaCo}_{0.9}\text{Ni}_{0.1}\text{S}_{1.95}$, we find a step in κ of almost one order of magnitude (times 6) and a large pressure shift, $\leq -24 \text{ K/kbar}$, which makes this material a potential pressure activated heat switch, while CuIr_2S_4 shows a small step of κ (times 1.2) and a pressure shift of $+2.8 \text{ K/kbar}$. © 1998 American Institute of Physics. [S0021-8979(98)40211-1]

I. INTRODUCTION

In the search for nongaseous cooling devices, pure solid state cooling has gathered renewed interest. With thermodynamic cycles, however, heat switches which connect and disconnect heat reservoirs have to be used. Solid state nonmechanical thermal switches at higher temperatures might be provided by metal-insulator MI transitions, as in metals the heat is often carried by electrons (Wiedemann-Franz law), while by phonons in insulators. Therefore, we have investigated the thermal conductivity of two recently found metal-insulator transitions, i.e., $\text{BaCo}_{0.9}\text{Ni}_{0.1}\text{S}_{2-y}$ and CuIr_2S_4 . For the first compound the metallic phase is at low temperatures; κ shows a step of times 6 at T_{MI} and T_{MI} has a large negative pressure shift, -24 K/kbar .¹ For the second compound the metallic phase is at high temperatures; κ changes by a factor of 1.2 at T_{MI} and T_{MI} shows a small positive pressure shift $+2.0 \text{ K/kbar}$.² Inverse behavior is also suggested by the specific heat capacity: the entropy change for CuIr_2S_4 is very high, 14 J/molK , suggesting an addition of electronic and lattice contribution and significantly lower for $\text{BaCo}_{0.9}\text{Ni}_{0.1}\text{S}_{2-y}$, 2.6 J/molK , suggesting a subtraction in this case.³ This means that the lattice entropy increases at T_{MI} in both cases while the electronic contribution is inverse, as expected.

II. EXPERIMENT AND RESULTS

The sample preparation and the experimental apparatus used are described in detail elsewhere.³⁻⁵ For the susceptibility measurements we have used the Faraday method and in some cases a superconducting quantum interference de-

vice (SQUID) magnetometer. The electrical conductivity and the Hall effect are measured using the four- and five-point method, respectively, while both the thermoelectric power and the heat diffusivity are taken from the initial amplitude and decay time of the transient thermoelectricity (TTE). The specific heat capacity data were obtained using a Perkin-Elmer DSC 2.

The temperature-independent susceptibility χ of nonmagnetic metals and insulators is usually written as the sum of Larmor (l), Landau, and Pauli (p) susceptibilities. For CuIr_2S_4 , the valence mixed configuration $(\text{Cu}^+\text{Ir}^{3+}\text{Ir}^{4+}\text{S}_4^{2-})$ gives $\chi l = -3.9 \times 10^{-7} \text{ emu/g}$ while $(\text{Cu}^+\text{Ir}_2^{3+}\text{S}_3^{-2})$ would give $\chi l = -3.8 \times 10^{-7} \text{ emu/g}$.³ Our experimental value, $\chi = -2.9 \times 10^{-7} \text{ emu/g}$ thus slightly favors a configuration of the second type. At low temperatures a Curie-type contribution of different magnitude⁶ always appears to be superimposed on χl , (Fig. 1) suggesting an impurity content of about 10^{-4} , which is close to the starting element purity. The constant positive Pauli-susceptibility χp in the metallic state, $T > T_{\text{MI}}$, has been used to estimate the density of states at the Fermi level. Our $\chi p = 8 \times 55 \times 10^{-7} \text{ emu/g}$ gives $N(E_F) = 1.66 \text{ states/eV atom}$ (literature value: 0.67 in these units⁶).

In the case of $\text{BaCo}_{0.9}\text{Ni}_{0.1}\text{S}_{2-y}$ a shallow maximum appears close to $T_N \approx 250 \text{ K}$, suggesting quasi-two-dimensional antiferromagnetic order.^{7,8} A spin compensated magnetic state also exists below T_{MI} , however long range magnetic order has not been found.⁹ Some random magnetic component is also suggested by the difference of $M(T)$ under zero field cooled (ZFC) and field cooled (FC) conditions (Fig. 1). Here, the field cooled magnetization curve for $T < T_{\text{MI}}$ differs slightly from the field warmed magnetization curve, but only when previously cooled in zero field.

In the metallic state of CuIr_2S_4 (compound I, Fig. 2), phonon scattering of the conduction carriers plus scattering on impurities (residual resistance, originating from impurities, vacancies, etc.), suffices to describe $\sigma = 1/\rho(T)$. In the

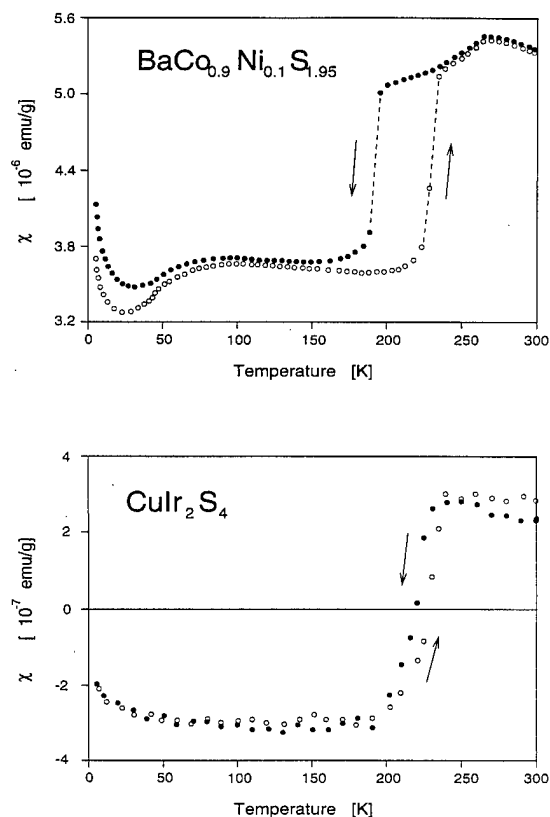

FIG. 1. Magnetic susceptibilities of CuIr_2S_4 and $\text{BaCo}_{0.9}\text{Ni}_{0.1}\text{S}_{2-y}$ vs temperature.

insulating state, activated behavior occurs. It is unclear, however, whether an Arrhenius law, $\ln(\rho/\rho_0) = -\Delta E/kT$, or a Mott law, $\ln(\rho/\rho_0) = -(T_0/T)^{1/4}$, better describes the resistivity in the insulating state, as the effective activation energy ΔE (or kT_0) changes strongly with the temperature (Fig. 2). Apparently, other CuIr_2S_4 samples can come closer to an Arrhenius law,⁶ suggesting a variable random component, most probably a sulfur deficit S_{4-y} .

The heat conductivity $\kappa(T)$ of CuIr_2S_4 (Fig. 2) shows only a small anomaly at the transition between the high temperature metallic state and the low temperature activated (semiconducting) state. This suggests a compensating effect. For nonmagnetic materials, the heat conductivity is usually written as a sum:¹⁰ $\kappa = \kappa_{\text{ph}} + \kappa_e$. As there is a structural change at T_{MI} , a phonon part κ_{ph} could indeed counteract an electronic part κ_e (Fig. 3). The ascending slope of κ below T_{MI} follows the general trend in insulators, $\kappa \sim 1/T^2$.¹⁰ An almost constant κ as observed in the metallic phase at high temperatures is typical for technical metals, i.e., suggests a large number of defects.

The linear dependence of S in the metallic phase suggests diffusion thermopower S_d ; from that $E_F \approx 1$ eV has been estimated.³ For the semiconducting phase, the thermal activation of the carriers determines S , e.g., $S = (k/e) \times (\Delta E/kT + \text{const.})$; assuming an Arrhenius law or, alternatively, $S \sim \sqrt{T}$ for a variable range hopping (VRH) regime.¹¹ VRH thus would explain the curved ascending part of $S(T)$ for $T < T_{\text{MI}}$.

Activated behavior occurs in the insulating phase of $\text{BaCo}_{0.9}\text{Ni}_{0.1}\text{S}_{2-y}$ (compound II), while $\sigma(T)$ is nearly con-

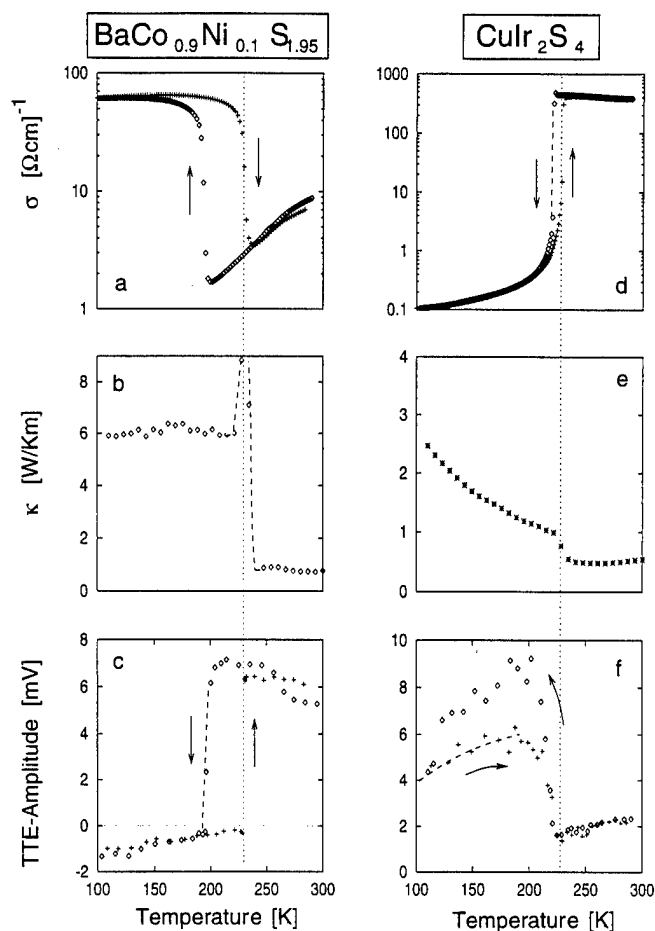

FIG. 2. Electrical and heat conductivities of CuIr_2S_4 and $\text{BaCo}_{0.9}\text{Ni}_{0.1}\text{S}_{2-y}$ vs temperature and the TTE amplitudes.

stant in the metallic state, again suggesting a large number of structural and/or spin defects.

The activation energy in the insulating state decreases with the pressure, -8 meV/kbar,¹ and increases with y , $+4.5$ meV/at. %.⁷ The y -dependence of the resistivity in the metallic state is stronger¹ as is the pressure dependence.^{1,7} This is probably due to increasing nonstoichiometry hole doping in the one case (y), while under pressure the carrier concentration would remain constant.

The conductivity κ is nearly constant, in the metallic state of $\text{BaCo}_{0.9}\text{Ni}_{0.1}\text{S}_{2-y}$, although for metals we expect

FIG. 3. Reconstruction of the step in heat conductivity at T_{MI} of CuIr_2S_4 and $\text{BaCo}_{0.9}\text{Ni}_{0.1}\text{S}_{2-y}$

FIG. 4. P - T phase diagram in reduced scales $\text{BaCo}_{0.9}\text{Ni}_{0.1}\text{S}_{2-y}$: $T_{M0} = 205, 230$ K, +, o : $P_c = 2$ and 2.9 kbar CuIr_2S_4 : $T_{M0} = 228$ K, $P_c = 2.9$ kbar.

$\kappa \sim 1/T$.¹² For the insulating phase, κ is almost constant, too, i.e., a $1/T^2$ law is not observed. A small structure appears close to the Néel point $T_N \approx 250$ K, suggesting a magnetic contribution, κ_m , which is numerically small. We observe a significant step in both κ and D_T at T_{MI} , with the higher heat conductivity in the metallic state, as expected. Either both κ_{ph} and κ_m are small, or change in the same direction as κ_e . For both compounds, the low temperature state has the lower symmetry^{6,9} and thus the step in κ_{ph} should run parallel to the step in κ_e in one case (II) and opposite in the other case (I), i.e., $\Delta\kappa_{ph}$ is not small and adds to $\Delta\kappa_e$ for compound II, while it subtracts for compound I (Fig. 3).

$S(T)$ of $\text{BaCo}_{0.9}\text{Ni}_{0.1}\text{S}_{2-y}$ changes abruptly at $T_{MI} = 230$ K. The zero crossing suggests two types of carriers and a two-band model. $S(T)$ of $y = 0.05$ indeed shows activated behavior in the semiconducting phase—a fit yields $\Delta E = 0.03$ eV as compared to 0.09 eV from $\rho(T)$.

In the metallic and magnetic state one should find two contributions for S : a magnetic, S_m , and an electron diffusion part, i.e., $S = S_m + S_d$.¹³ While the smaller negative values of S below T_{MI} are consistent with a metallic regime and electrons, the small ascending slope below T_{MI} is not consistent with electron diffusion and thus suggests magnon or phonon drag.

With increasing pressure, the MI transition of $\text{BaCo}_{0.9}\text{Ni}_{0.1}\text{S}_{2-y}$ shifts to low temperatures, and the resistivity step at the transition increases. The critical pressure P_c at which the MI transition does not occur anymore (Fig. 2), is higher for higher $T_{MI} = T_c$, that is for larger y . In Fig. 4, the similarity of the P - T diagrams for two compounds with different y has been demonstrated by using reduced variables T/T_c and P/P_c . The compounds with smaller y can thus be regarded as a “precompressed” compounds in relation to the highest sulfur deficit $y \leq 0.15$, i.e., we may consider an effective lattice contraction as a result of the action of the internal (structural or chemical) and external pressure, with a conversion ratio of about 1.5 at. %/kbar. With T and P critical but numerically different for various y , the concept of a critical volume at which the transition always occurs has been put forward.⁵

III. PHASE TRANSITION MODELS

The idea of a critical volume in $\text{BaCo}_{0.9}\text{Ni}_{0.1}\text{S}_{2-y}$ is consistent with the microscopic model of this MI transition as

proposed by Philips.^{15,16} here, it is proposed that the high temperature semiconducting state is stabilized through screening of the electrostatic charges by thermally activated carriers. At low temperatures the carriers freeze out, increasing the electrostatic energy of the crystal and a new (better screening, i.e., metallic) ground state may be installed. The introduction of many electronic states close to the Fermi-level of the metallic phase via the distortion would further stabilize the metallic phase (Fermi-level pinning/anti-Jahn-Teller effect¹⁶). Several observations are consistent with this approach: for example, applying pressure reduces the energy gap, -8 meV/kbar,¹ thus prolonging the activated carrier screening and indeed the insulating state is stabilized under pressure.

The nature of the transition in CuIr_2S_4 is still unclear. A valence mixture of iridium, say $\text{Ir}^{+3}/\text{Ir}^{+4}$, which might drive the change of state in a Verwey-type of transition, has been ruled out.⁶ Because of the cubic-tetragonal lattice distortion at T_{MI} the transition has been classified as Jahn-Teller-like. The $(t_{2g})^4$ orbital of Ir in octahedral configuration is twofold degenerate and could be split by distortion. However, as the observed distortion is rather small and as a Jahn-Teller effect has not been observed directly, the distortion might not be the driving force but a secondary or coupled order parameter. Thus, alternatively, a condensation of quasiparticles (e.g., Jahn-Teller-polarons) into a gap state has been discussed.¹⁴

Magnetocrystalline anisotropy of $(\text{Fe}_{1-x}\text{Co}_x)_3\text{P}$

A. Broddefalk,^{a)} P. Granberg, and P. Nordblad

Department of Materials Science, Uppsala University, Box 534, S-751 21 Uppsala, Sweden

Hui-ping Liu and Y. Andersson

Department of Inorganic Chemistry, Uppsala University, Box 538, S-751 21 Uppsala, Sweden

The magnetocrystalline anisotropy energy (MAE) of $(\text{Fe}_{1-x}\text{Co}_x)_3\text{P}$ ($x=0, 0.1, 0.2, 0.33$) has been studied in the temperature range 5 K–300 K. The compound crystallizes in a tetragonal structure with three non-equivalent metal sites and shows an easy planar behavior with the magnetic moments aligned in the ab plane and the c axis as the hard direction. The MAE of Fe_3P was investigated using magnetization measurements on a single crystalline sample. The anisotropy constants were found to be $K_1 \approx -851 \text{ kJ/m}^3$ and $K_2 \approx 9 \text{ kJ/m}^3$ at 5 K and $K_1 \approx -648 \text{ kJ/m}^3$ and $K_2 \approx 11 \text{ kJ/m}^3$ at 300 K. The MAE of the cobalt substituted systems was investigated on sintered samples formed into spheres. K_1 for these samples was calculated from a fit of the magnetization versus internal field strength using the law of approach to saturation. © 1998 American Institute of Physics. [S0021-8979(98)51511-3]

I. INTRODUCTION

Among the T_3X compounds ($\text{T}=3\text{d}$ element and $\text{X}=\text{nonmetal element}$), ordered magnetic structures are only found for $\text{X}=\text{P}$ and group IV elements.¹ The phosphides crystallize in a tetragonal system where Fe_3P is ferromagnetic, Mn_3P is antiferromagnetic and Ni_3P and Cr_3P are Pauli paramagnetic.^{2,3} The Co_3P phase does not exist in the binary Co-P system.⁴ In previous studies of the magnetic properties of $(\text{Fe}_{1-x}\text{M}_x)_3\text{P}$ ($\text{M}=\text{Cr, Mn, Co, Ni}$) no information about the magnetocrystalline anisotropy can be found.^{2,3}

$(\text{Fe}_{1-x}\text{Co}_x)_3\text{P}$ ($x<0.37$) crystallizes in the tetragonal Fe_3P structure (see Fig. 1). In a previous report,⁵ structural and magnetic properties, such as the individual moments of each magnetic atom and the Curie temperature, were described. The total magnetic moment, the critical temperature as well as the cell parameters were found to decrease with increasing cobalt concentration. Neutron diffraction experiments on samples with compositions $x=0.1$ and $x=0.33$ showed that the Co distribution is approximately 20% on position M(1) and 40% on both M(2) and M(3) (see Fig. 1). From magnetization measurements on oriented grains, performed by Meyer and Cadeville,⁶ the anisotropy constants of Fe_3P were found to be $K_1 = -530 \text{ kJ/m}^3$ and $K_2 = 240 \text{ kJ/m}^3$. Magnetization measurements on single crystal Fe_3P made by Lisher *et al.*⁷ showed an easy-planar behavior with an anisotropy in the basal plane of 2 kJ/m^3 .

Close to saturation, the magnetization process is governed by the magnetocrystalline anisotropy energy (MAE) and the magnetostatic energy. In a uniaxial crystal, the MAE may be expressed as $E_a = K_1 \sin^2 \theta + K_2 \sin^4 \theta + \dots$ where θ is the angle of the magnetization with respect to the unique axis. For the easy-axis case, $K_1 > 0$, while for the easy-planar case, $K_1 < 0$. For the easy-planar case, with an applied field H_a parallel to the unique axis, the magnetization at equilibrium is given by

$$H_a = \left[\frac{-(2K_1 + 4K_2)}{\mu_0 M_s^2} + N \right] M + \frac{4K_2}{\mu_0 M_s^4} M^3, \quad (1)$$

where N is the demagnetization factor and M_s the saturation magnetization. In the polycrystalline case, one has to take an average over all possible orientations. Provided that $|K_1| \gg |K_2|$, an expansion of M up to the third-order term leads to^{8,9}

$$M = M_s \left[1 - \frac{1}{15} \left(\frac{2K_1}{\mu_0 M_s} \right)^2 \frac{1}{H^2} - \frac{2}{105} \left(\frac{2K_1}{\mu_0 M_s} \right)^3 \frac{1}{H^3} \right], \quad (2)$$

where H is the internal magnetic field. K_1 can thus be obtained from a fit of the magnetization according to

FIG. 1. The crystal structure of Fe_3P projected on the (001) plane.

^{a)}Electronic mail: arvid.broddefalk@material.uu.se

FIG. 2. Saturation magnetization vs temperature for $(\text{Fe}_{1-x}\text{Co}_x)_3\text{P}$. M_s is derived from fits of the experimental magnetization curves to the law of approach to saturation.

$$M = M_s \left(1 - \frac{b}{H^2} - \frac{c}{H^3} \right). \quad (3)$$

This equation is called the law of approach to saturation. The determination of K_1 using this method has some drawbacks. The magnetization rotation is not the only process involved. Local fields due to inhomogeneities and field induced increased spontaneous magnetization complicate the M vs H behavior. Instead of Eq. (3), the law of approach to saturation obtained by experiment is

$$M = M_s \left(1 - \frac{a}{H} - \frac{b}{H^2} - \frac{c}{H^3} \right) + \chi H, \quad (4)$$

where a is an inhomogeneity parameter and χ is the susceptibility, which also takes care of a dia- or paramagnetic contribution from the sample holder.

FIG. 3. K_1 vs T for $(\text{Fe}_{1-x}\text{Co}_x)_3\text{P}$. The estimated error in the data points due to scatter in the raw data and an uncertainty in the fitting procedure are about 40 kJ/m^3 for $x=0, 0.2$ and 0.33 and about 60 kJ/m^3 for $x=0.1$. The difference is due to a difference in the sample masses.

FIG. 4. K_1 at three different temperatures vs x .

II. EXPERIMENTS AND RESULTS

A single crystal disc of Fe_3P with the c axis in the disc plane was measured in a Quantum Design MPMS 5.5 T superconducting quantum interference device (SQUID) magnetometer. The magnetocrystalline anisotropy constants K_1 and K_2 were obtained by fitting H_a vs M data to Eq. (1). K_2 was found to be small and positive ($K_2 < 20 \text{ kJ/m}^3 \ll |K_1|$). Magnetization measurements on spherical sintered samples of $(\text{Fe}_{1-x}\text{Co}_x)_3\text{P}$ were carried out in a 5 T LakeShore magnetometer. The M vs H curves were analyzed using Eqs. (2) and (4). An easy planar behavior with $K_2 \ll |K_1|$ has thus been assumed for all temperatures and for all Co concentrations. For all the samples, the a/H term was omitted since the curve fits were not improved by it. In Fig. 2 the temperature dependence of the saturation magnetization is shown. The anisotropy constants of the different samples is plotted versus temperature in Fig. 3. In this region of Co concentration, the critical temperature decreases almost linearly from 692 K for $x=0$ to 646 K for $x=0.33$.⁵

The systematic difference in magnitude of K_1 for Fe_3P as derived from measurements on the single crystal compared to the results from the polycrystalline sample is probably due to some inadequacy in the derivation of K_1 from Eq. (4) using a limited field interval (9 kOe–50 kOe). The relative variation of K_1 with temperature and Co concentration should however be adequately captured. $|K_1|$ decreases quite regularly with temperature for all the samples. It is noticeable however that there is an increase of $|K_1|$ with x at low Co concentrations followed by a clear decrease at large values of x (see Fig. 4). First principles calculations of the MAE of $(\text{Fe}_{1-x}\text{Co}_x)_3\text{P}$ (Ref. 10) are now in progress.

Magnetic moment and hyperfine field on Fe sites in $R\text{Fe}_6\text{Sn}_6$ compounds

Xiao-lei Rao,^{a)} J. Cullen, V. Skumryev, and J. M. D. Coey

Department of Physics, Trinity College Dublin, Dublin 2, Ireland

Electronic structure and hyperfine fields are calculated for antiferromagnetic YFe_6Sn_6 using the linear muffin-tin orbital method. The results show that Fe atoms have a strong ferromagnetic character with a full majority-spin band. The Fe moment is $2.2 \mu_B$ while the Fermi contact term contributes a hyperfine field of 20 T at the natural lattice parameters. The hyperfine field is close to the experimental value of 22 T measured at low temperature. The calculation shows that the core s electrons contribute 24 T to the hyperfine field, but the $4s$ electron contributes 4 T in the opposite direction. Calculations using different unit cell volumes reveal that only the core electron contributions to the hyperfine field are proportional to the Fe magnetic moment with a conversion factor of $11.8 \text{ T}/\mu_B$; the $4s$ contribution is not. The large local Fe moment and small hyperfine field are similar to those found in Fe_2P and FeO . © 1998 American Institute of Physics. [S0021-8979(98)51611-8]

I. INTRODUCTION

Fe-based heavy rare earth stannides of chemical formula $R\text{Fe}_6\text{Sn}_6$ with HfFe_6Ge_6 -derived crystal structures were first reported by Malaman *et al.*¹ and by Wang *et al.*² The rare-earth atoms and Sn–Sn dumbbell pairs in $R\text{Fe}_6\text{Sn}_6$ occupy a single crystallographic site in the HfFe_6Ge_6 -type unit cell in a complex way which makes otherwise equivalent Fe sites distinguishable. The nearest Fe–Fe distances are around 2.68 Å, 5% larger than in $\alpha\text{-Fe}$. The well-separated Fe atoms lead to strong ferromagnetism with a large magnetic moment. Recently we reported the results of a ^{57}Fe Mössbauer study of $R\text{Fe}_6\text{Sn}_6$ ($R=\text{Y}$, Gd, Tb, Dy, Ho, Er, and Tm) at room temperature and at 25 K.³ The spectra show a single sextet even though there are several Fe inequivalent iron sites in the unit cell. Hyperfine fields are almost the same for all R elements. At 25 K the values are around 22 T which would imply an average Fe moment of $1.5 \mu_B$ with the usual conversion factor of $15 \text{ T}/\mu_B$ found in many R–Fe compounds,⁴ $0.7 \mu_B$ less than $\alpha\text{-Fe}$. Because of the antiferromagnetism, the value of the Fe moment is difficult to obtain from magnetization measurements without a very high field.

Here we study the electronic structure and hyperfine fields of YFe_6Sn_6 using the linear muffin-tin orbital (LMTO) method in order to examine the relation between magnetic moment and hyperfine field on Fe sites. Calculations were made on expanded and contracted unit cells as well as at the natural cell volume.

II. BAND CALCULATION METHOD

The crystal structure of YFe_6Sn_6 is derived from the HfFe_6Ge_6 -type unit cell (Fig. 1) described by space group $P6/mmm$ where Fe 6i sites form planar layers. Ideally, the Y atoms occupy the Hf-1b site while Sn atoms enter into Ge-2c and Ge-2d sites and dumbbell Ge-2e sites. However real YFe_6Sn_6 crystallizes in a far more complex structure defined by the space group $Cmcm$ with 208 atoms and 9

inequivalent Fe sites in each unit cell. This complexity comes from the distribution of Y atoms and Sn–Sn 2e dumbbell pairs among the Hf-1b sites. Since the Mössbauer spectrum of the compound did not differentiate the Fe sites, an approximation is made to simplify the complex structure: we used the HfFe_6Ge_6 -type structure to define the unit cell and to assign the atomic positions according to the HfFe_6Ge_6 -type TmFe_6Sn_6 .⁵ Detailed information is shown in Table I. The lattice parameters of YFe_6Sn_6 , $a=5.371 \text{ Å}$ and $c=8.894 \text{ Å}$, are taken from the experimental x-ray diffraction pattern based on the HfFe_6Ge_6 -type structure. The ratio of c/a is kept constant for calculating the band structures for varied unit cell volumes. Concerning the magnetic structure, we assume a ferromagnetic coupling within the Fe layer and an antiferromagnetic coupling between the layers within one unit cell. Because of this antiferromagnetic coupling, the unit cell has to be doubled along the c direction to allow for the crystallographic and magnetic symmetry.

The LMTO⁶ has been employed within the atomic spheres approximation (ASA). Exchange and correlation interactions were treated with the local spin density functional (LSDF) approximation, using the form given by von Barth

FIG. 1. The unit cell of HfFe_6Ge_6 .

^{a)}Electronic mail: huanlab@aphy02.iphy.ac.cn

TABLE I. Crystallographic data used for the YFe_6Sn_6 band calculations.

Compounds	Structure type	Space group	Atomic position		
YFe_6Sn_6	HfFe_6Ge_6	hP13 ($P6/mmm$, No. 191)	Fe	6i	(1/2, 0, 0.251)
			Sn1	2e	(0, 0, 0.162)
			Sn2	2d	(1/3, 2/3, 1/2)
			Sn3	2c	(1/3, 2/3, 0)
			Y	1b	(0, 0, 1/2)

and Hedin⁷ and by the parameters used by Janak.⁸ The scalar-relativistic approximation was used without considering the spin-orbit coupling.⁹ In the ASA, in most cases there is a reasonable region for choosing the ratio of the Wigner-Seitz sphere radii for different elements which only results in a variation of calculated moments of $0.05 \mu_B$ per magnetic atom, even smaller than the neglected orbital contribution. In the calculations reported here, the ratio $r_Y:r_{\text{Fe}}:r_{\text{Sn}}$ of 1.35:1:1.1 was chosen. With the experimental lattice parameters, the maximum overlap of the atomic spheres is less than 25%, which ensures a reliable convergence of the self-consistent calculations. The basis set of valence states is $4s$, $4p$, and $3d$ for Fe and $5s$, $5p$, and $4d$ for Y and Sn. The number of k points in the irreducible part of the Brillouin zone on which the calculation of the self-consistent potential was based was chosen to be 84. The total energy converged to within 10^{-4} Ry.

III. RESULTS AND DISCUSSION

The density of states (DOS) of the Fe $3d$ band in YFe_6Sn_6 with the natural lattice parameters and at 12.5% volume expansion or contraction are shown in Fig. 2. In all cases the majority and minority $3d$ bands are well split, with the Fermi level above the majority band, a typical feature for a strong ferromagnet. This is the result of the large Fe-Fe nearest-neighbor distance in YFe_6Sn_6 . The trend was clearly demonstrated on α -Fe band structures with different lattice parameters: its magnetic state at the natural lattice parameter $a=2.86 \text{ \AA}$ is a weak ferromagnet. At larger lattice parameters, the $3d$ electrons become more localized. The bandwidth decreases and the Fermi level shifts towards the top of the spin-up subband. When the lattice parameter reaches 2.96 \AA (the Fe-Fe distance is 2.56 \AA), the $3d$ spin-up band is full. The ferromagnetic state now has a strong ferromagnetic character. Since there are no other electrons available, the increased states in the spin-up band of α -Fe can only be filled by its spin-down $3d$ electrons. The net magnetic moment increases until strong ferromagnetism is realized. In comparison, the Fe-Fe distance in YFe_6Sn_6 is 2.68 \AA . A strong ferromagnetic feature is expected when the lattice parameter dependence is similar to that of α -Fe. The long tail with energy below -0.3 Ry is due to the Sn hybridization, which can be recognized by the Sn- $2e$ band (inset in Fig. 2).

The calculated magnetic moment of Fe, which is $2.2 \mu_B$ at the experimental lattice parameters, is much higher than the value estimated from Mössbauer spectra but lower than the moment in α -Fe with the same Fe-Fe distance. Charge transfer and hybridization of neighboring Sn electrons reduce

FIG. 2. The density of states at iron sites in YFe_6Sn_6 with (a) 12.5% volume contraction, (b) natural unit cell volume, and (c) 12.5% expansion. Inset is the DOS of the Sn- $2e$ site.

the value of the moment. The corresponding hyperfine field is -20 T . As the lattice parameters vary, both the magnetic moments [Fig. 3(a)] and the absolute value of hyperfine fields [Fig. 3(b)] increase with enlarged unit cell volumes. The $4s$ contribution to the hyperfine field which increases linearly with the unit cell volume is opposite to the core contributions in direction. The latter feature is quite different from most of the R-T intermetallics where both contributions are in the same direction, resulting in larger total hyperfine fields. The reason is that the $4s$ valence electrons are polarized in the same direction as the Fe $3d$ moment. In many other R-Fe compounds, where the Fe $3d$ bands have a weak ferromagnetic character because the average Fe-Fe distance is only about 2.55 \AA , the $4s$ - $3d$ hybridization then pushes the $4s$ majority weight above the Fermi level and leads to less $4s$ majority occupation. The opposite phenomenon occurs for the minority band. This results in a negatively polarized $4s$ shell, whose contribution to the hyperfine field is in the opposite direction to the Fe $3d$ moment but in the same direction as the core s electron hyperfine field. However in the strong magnetic state as in YFe_6Sn_6 , the

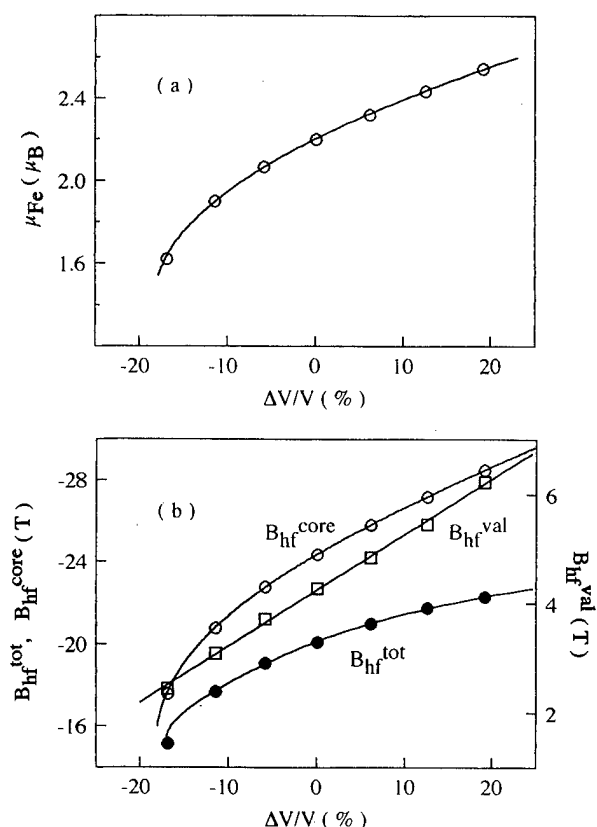

FIG. 3. Unit cell volume dependence of (a) Fe magnetic moments and (b) Fe hyperfine fields in YFe_6Sn_6 .

majority 3d band is full. Direct ferromagnetic 4s mixing into the majority band dominates the above antiferromagnetic hybridization. The hyperfine field of the 4s electrons is in the same direction as Fe moment. Similar behavior was reported by Eriksson *et al.* for the Fe_2P and FeO hyperfine interactions¹⁰ because in both cases the Fe atoms are strongly ferromagnetic.

Upon plotting the hyperfine fields against magnetic moments on Fe sites for different unit cell volumes, as shown in Fig. 4, only the contribution of core electrons to the hyperfine field increases linearly with the local moment. The non-linear relation between the valence 4s electron term in the hyperfine field makes the relation between the magnetic moment and the total hyperfine field deviate from linearity. The slope of the core electron contribution is 11.3 T/ μ_B , just at the lower limit of the data observed experimentally. The total hyperfine field at the natural cell volume is 20 T, 10% lower than the experimental value measured at 25 K. This may be attributed to an overestimate of the valence contributions since the DOS already shows that the covalent tendency is

FIG. 4. The hyperfine fields as a function of magnetic moments on Fe sites in YFe_6Sn_6 with different unit cell volumes.

relatively strong for the $\text{Fe}6i\text{-Sn}2e$ neighbors. The LMTO method has limited power in handling less itinerant systems.

IV. CONCLUSION

Because of the strong ferromagnetic character of the Fe electronic structure due to the large Fe-Fe nearest-neighbor distance and because of the electron transfer from neighboring Sn atoms, the Fe atoms in YFe_6Sn_6 bear a large magnetic moment of 2.2 μ_B but show a relatively small hyperfine field of only 20 T. Proportionality of hyperfine fields and magnetic moments on the Fe sites only holds for the core electron contribution or when the valence electron contribution to the hyperfine field is negligible.

Neutron diffraction was used to determine the deuterium sites in TbNiAlD_{1.28} and TbNiAlD_{0.8}. Both samples were found to crystallize in the orthorhombic Amm2 space group. Our analysis reveals that deuterium in TbNiAlD_{1.28} occupies positions at $x=0$ and $x=1/2$ only, while TbNiAlD_{0.8} shows the formation of two different phases. For TbNiAlD_{1.28}, additional magnetic reflections are observed below 16 K indicating antiferromagnetic order. On the other hand, at 10 K, only one of the TbNiAlD_{0.8} phases was found to be magnetic. In addition, our study of the localized vibrations of hydrogen in TbNiAlH_{1.39} and in its non-magnetic analog YNiAlH_{1.35} using inelastic neutron scattering supports the existence of two different hydrogen sites in the saturated hydrides. © 1998 American Institute of Physics. [S0021-8979(98)33611-7]

Although hydrides of intermetallic compounds are used extensively as hydrogen-storage media,¹ little is known about the exact nature of metal-hydrogen interactions. However, this knowledge is of essential importance for the understanding of thermodynamic and other properties.

Magnetic order in intermetallic TbNiAl is based on well-defined $4f$ moments, which are coupled by indirect exchange interaction of *RKKY* type. Ehlers and Maletta² found that this compound undergoes two magnetic phase transitions around 23 and 47 K, forming complex magnetic structure. They reported, based on neutron-diffraction data, that magnetic ordering occurs in two Tb sublattices, described by two different propagation vectors, i.e., $\mathbf{q}=(1/2,1/2,1/2)$ and $\mathbf{q}=(1/2,0,1/2)$. Recently, it was shown that introduction of hydrogen (deuterium) into TbNiAl can lead to drastic alterations of its magnetic properties.³ Furthermore, x-ray studies revealed that hydrogenation (deuteration) is accompanied by orthorhombic distortion of the hexagonal ZrNiAl-type structure,⁴ adopted by pure TbNiAl, but the location of H(D) atoms in the crystal lattice remained unknown.

Here we report on some properties (crystal and magnetic structures, lattice vibration) of TbNiAl hydrides and deuterides studied by means of neutron diffraction and inelastic neutron scattering.

Samples were prepared by arc melting. Several remeltings were done in order to achieve high homogeneity. Crystal structure of the obtained compound had been checked by x-ray analysis, which confirmed that it was a single-phase TbNiAl polycrystal. Hydrides (deuterides) were obtained as follows: first, the intermetallic compound was crushed and activated in the high vacuum of $\sim 10^{-6}$ Torr at 350 °C for 1

h, afterwards it was cooled down to room temperature and exposed to H(D) at 10 atm pressure. Amount of absorbed H was determined by monitoring decrease of pressure in the calibrated volume. In order to obtain the lower deuteride, the saturated sample was heated up to 155 °C and kept at this temperature until pressure has stabilized. Then the reaction chamber was disconnected from the hydrogenation system and cooled down to the room temperature. X-ray analysis was used to check to quality of the resulting compounds.

For the neutron-diffraction experiments, powder samples of TbNiAlD_{1.28} and TbNiAlD_{0.8} were ground and sealed in vanadium tubes under helium atmosphere. Diffraction data were taken at various temperatures between 5 and 300 K using the powder diffractometers NPD and HIPD at the Lujan Center. NPD is a high-resolution diffractometer, used for crystal-structure refinements, with four detector banks covering d -spacings up to 4 Å, while HIPD is a high-intensity diffractometer, well suited for magnetic-structure refinements, with eight detector banks covering a range up to 20 Å. The data were analyzed by using the Rietveld-refinement program package GSAS.⁵

For the inelastic-neutron-scattering studies, hydrogenated samples of YNiAlH_{1.35} and TbNiAlH_{1.39} were sealed under helium atmosphere in aluminum cans. Measurements were performed at low temperatures using the filter difference spectrometer (FDS) at the Lujan Center. The spectra shown in Fig. 3 are obtained by numerical deconvolution of the instrumental function from the raw data.⁶

Our Rietveld refinements on TbNiAlD_{1.28} and TbNiAlD_{0.8} indicate that both compounds form in the base-centered orthorhombic space group Amm2, with structural parameters as given in Tables I and II, respectively. Using an orthorhombic notation, a hexagonal unit cell can be described by the parameters a , b , c , and $b=a\sqrt{3}$. If the hexagonal structure is distorted, we get $a/b \neq \sqrt{3}$. Here we cho-

sed to use the standard notation of the space group Amm2, defined for this structure. Therefore, in the present article the coordinates a and c are interchanged, comparing to the notation mentioned above.

Atom fractions of Tb, Ni, and Al were found to be very close to the exact 1:1:1 stoichiometry, and we subsequently refined only the D fractions in the two samples.

The room-temperature refinement on TbNiAlD_{1.28} clearly indicates that only two different fourfold interstitial positions are occupied by D atoms (Table I) (which seems to be in contradiction to four different D positions in TbNiAlD_{1.04}, recently reported by Yartys *et al.*⁷). The resulting structure is shown in Fig. 1.

The diffraction data on the second sample (which had a nominal composition of about TbNiAlD_{0.8}) indicate the formation of two phases with quite different lattice parameters. The GSAS software package allows the parallel refinement of multiple phases, and our best fit yielded two phases: a main phase of TbNiAlD_{0.81} and an "impurity phase" of TbNiAlD_{0.83} with volume fractions of about 70% and 30%, respectively. The structure of the main phase is found to be closely related to those of TbNiAlD_{1.28} (Table II) with the D occupying positions in the $x=0$ and $x=1/2$ planes only. For

FIG. 1. Crystal structure at room temperature of TbNiAlD_{1.28} and TbNiAlD_{0.8} (main phase).

the impurity phase, on the other hand, we have indications that the D atoms are located between those planes. However, data on a single-phase sample are needed in order to determine their exact positions. The structure of the main phase (TbNiAlD_{0.81}) is the same as the one shown in Fig. 1. For both phases, we find that only a fraction of the D positions are occupied (see Table II).

For both samples, magnetic ordering sets in at low temperatures. In TbNiAlD_{1.28}, the HIPD data revealed two extra peaks at 7.21 and 12.90 Å, which occur below 16 K [Fig. 2(a)]. These reflections are magnetic in origin and can be indexed in the Amm2 cell with doubled a and b axis, indicating a magnetic propagation vector of $\mathbf{q}=(1/2,1/2,0)$. Similarly, in the biphasic sample (TbNiAlD_{0.8}), magnetic reflections are seen at the 20 K NPD data, which are absent at room temperature [Fig. 2(b)]. Closer inspection reveals that some magnetic contributions can be indexed assuming a cell doubling of a and b axis of the main phase, where the D atoms occupy $x=0$ and $x=1/2$ positions.

These findings provide evidence that D may occupy different positions in the crystal lattice, and magnetic properties of the material are strongly dependent on the location of those atoms. The location of D (H) in these materials seems to be extremely sensitive to small differences in such conditions, as sample preparation, aging, etc. This may explain recent bulk magnetic results, where different behavior was reported for some TbNiAl deuterides and hydrides with equal nominal compositions.³ Furthermore, our neutron results indicate a ratio between main and impurity phases of TbNiAlD_{0.8} of about 3:1, while x rays performed some few months earlier indicated a phase ratio of 10:1 only.⁸ This may indicate that (some of) the phases are not stable enough and decomposition or phase transformation may influence the properties in addition. A detailed study of samples with different history is required in order to confirm this.

Hydrogen vibrations in metals can be observed only by inelastic neutron scattering, which selectively probes hydrogen motions because of the large neutron scattering cross

FIG. 2. Portion of the powder patterns for (a) TbNiAlD_{1.28} taken at 14 and 16 K on HPD, and (b) TbNiAlD_{0.8} taken at 10 K and at room temperature on NPD. Magnetic reflections seen at low temperature in the upper panels are marked by arrows.

section of hydrogen. The vibrational spectra of hydrogen for TbNiAlH_{1.39} and its nonmagnetic⁹ analog, YNiAlH_{1.35}, measured at 40 and 20 K, respectively, are displayed in Fig. 3. The deconvoluted spectra were fitted using a Gaussian line shape for the peaks. The results are shown as solid lines in Fig. 3.

The YNiAlH_{1.35} spectrum shows three main bands at about 430, 937, and 1200 cm⁻¹. In addition, shoulders at 540, 832, and 1055 cm⁻¹ can be distinguished. The results are very similar to those obtained on LaNi₅H_{0.15}.¹⁰ In that work, the existence of two H sites was assumed, because, in absence of any degeneracy, each H site gives rise to three vibrations modes. NMR measurements on YNiAlH_x by Bandyopadhyay *et al.*¹¹ also indicate that H occupies two different interstitial sites, with different degrees of mobility.

FIG. 3. Inelastic-neutron-scattering results of (a) YNiAlH_{1.35} at 20 K and (b) TbNiAlH_{1.39} at 40 K. The gaussian fits represent the localized hydrogen vibrations.

Therefore, we may assume a similar assignment of the modes observed in YNiAlH_{1.35}: the strong bands are characteristic for the first hydrogen site, while the shoulders may be assigned to the second site.

Our spectrum of TbNiAlH_{1.39} is similar to the spectrum of YNiAlH_{1.35}: main vibrational bands observed at 449, 935 (with shoulder at 857 cm⁻¹), and 1203 cm⁻¹ (with shoulder at 1110 cm⁻¹). However, the scattering intensity around 540 cm⁻¹ is now split into two peaks, which are located at 535 and 606 cm⁻¹, respectively.

In conclusion, we propose an assignment of the vibrational modes YNiAlH_{1.35} and TbNiAlH_{1.39} to specific H sites. Nevertheless, a reliable assignment of the modes is possible only with the aid of calculations. For this purpose, we have initiated a vibrational analysis for these systems.

Thermal transport in $\text{Sr}_{1-x}\text{Ca}_x\text{RuO}_3$

M. Shepard, P. F. Henning,^{a)} G. Cao, and J. E. Crow

National High Magnetic Field Laboratory, 1800 E. Paul Dirac Drive, Tallahassee, Florida 32306

We have studied the thermal conductivity $K(T, B)$ ($6 < T < 250$ K, $0 < B < 15$ T) of single crystals of SrRuO_3 , a ferromagnet with $T_c = 160$ K, and isostructural but paramagnetic CaRuO_3 , as well as the intermediate crystals $(\text{Sr}, \text{Ca})\text{RuO}_3$ for the purpose of probing charge carrier (K_e), phonon (K_p), and magnon (K_m) excitations in these systems. The contributions of electron and phonon scattering processes to the thermal conductivities have been estimated using a Wiedemann-Franz relationship to estimate K_e and thus obtain K_p at higher temperatures. Roughly 50% of the thermal conductivity is estimated to be phononic near room temperature. Amorphous behavior is observed in the doped samples, and no break in the thermal conductivity is seen at the ferromagnetic onset. A comparison of magnetothermal conductivity and magnetoresistivity measurements at lower temperatures in SrRuO_3 and CaRuO_3 reveals that additional scattering mechanisms have become important. These investigations argue for the importance of phonon and magnon contributions, in addition to electronic contributions, to the magnetic behavior in $\text{Sr}_{1-x}\text{Ca}_x\text{RuO}_3$. Results will be discussed in relation to recent theoretical work on these systems and measurements on related systems. © 1998 American Institute of Physics. [S0021-8979(98)33711-1]

I. INTRODUCTION

SrRuO_3 and CaRuO_3 along with the mixed crystals, i.e., $(\text{Sr}, \text{Ca})\text{RuO}_3$ are interesting systems where electron correlations and lattice distortions may have a profound impact on their ground state electronic and magnetic properties.¹ Although SrRuO_3 and CaRuO_3 are isostructural, crystallizing in a distorted perovskite structure with similar lattice parameters, SrRuO_3 is an itinerant ferromagnet with $T_c = 160$ K, while CaRuO_3 remains paramagnetic to 30 mK apparently due to a slightly more distorted structure, due to Ca's smaller ionic radius ($\text{Sr} = 1.18$ Å vs $\text{Ca} = 1.00$ Å). The stark contrast between SrRuO_3 and CaRuO_3 is surprising because the s -like character of Sr and Ca do not have a density of states at the Fermi surface and therefore should not be a driving force for the ground states of these two compounds.² This lack of sensitivity of the magnetic ground state to Sr and Ca suggest that lattice distortions may play a dominant role in determining their ground states. The sensitivity of the magnetic ordering to small structural changes is similar to the behavior seen in ferromagnetic lanthanum manganite perovskites,³ where the Mn-O-Mn bond angle is important to the magnetic ground state and magnetic ordering temperature. Recently, work presented on the magnetic and transport properties of $\text{Sr}_{1-x}\text{Ca}_x\text{RuO}_3$ single crystals indicates a steady decrease in the ferromagnetic transition temperature as the Ca concentration is increased, with signs of magnetic ordering appearing at as low a concentration as $x = 0.99$, i.e., 1% Sr in CaRuO_3 .⁴ In addition, the easy axis for magnetization within the ferromagnetic state of SrRuO_3 is in the ab plane and rotates out of the ab plane with increasing Ca doping. The magnetic hysteresis also appears to increase with increasing x for the mixed crystals. Since local lattice distortions appear to drive the magnetic ground state behavior of

the $(\text{Sr}, \text{Ca})\text{RuO}_3$ system, thermal conductivity measurements may be a useful probe of coupling of the lattice, i.e., phonons, to the magnetic and electronic excitations.

Recent studies of the thermal conductivity in the lanthanum manganites indicate a large lattice contribution to the thermal conductivity, as well as a strong link between the lattice and the magnetic properties.^{5,6} The field dependence of the thermal conductivity of SrRuO_3 has been recently reported and evidence for magnons below the ordering temperature and coupling of the lattice to the magnons is demonstrated.⁷ In this article, the behavior of the thermal conductivity in $\text{Sr}_{1-x}\text{Ca}_x\text{RuO}_3$ will be presented and discussed in the framework of the contributions of electrons and phonons to the total thermal conductivity, as well as to the nature of the ferromagnetism.

II. EXPERIMENTAL RESULTS AND DISCUSSION

Single crystals of SrRuO_3 and CaRuO_3 were grown by a flux growth technique described previously.⁴ The thermal conductivity was measured by a standard steady-state one heater, two thermometer technique. The thermometers used were $12.5\ \mu\text{m}$ type E differential thermocouples; magnetic field dependences of the thermocouples were corrected.⁸ The heater was a $100\ \Omega$ RuO_2 chip heater with little temperature variation of the resistance over the temperature range of interest. The base temperature was monitored with a Cernox thermometer. Field was parallel to the c axis and the heat flow was applied along the a - b plane. Resistivity measurements were made using a standard four-probe dc technique, with field applied parallel to the c axis and current flow applied in the ab plane. Errors in the absolute values of the measurements are limited by the size of the samples, typically $0.4\ \text{mm} \times 0.4\ \text{mm} \times 0.1\ \text{mm}$, with an error from size calculations determined to be $< 10\%$.

In Fig. 1 is shown the thermal conductivity $K(T)$ versus temperature measured for several $\text{Sr}_{1-x}\text{Ca}_x\text{RuO}_3$ crystals.

^{a)}Present address: Department of Physics, Brookhaven National Laboratory, Upton, NY.

FIG. 1. Thermal conductivity vs temperature for $\text{Sr}_{1-x}\text{Ca}_x\text{RuO}_3$. The ferromagnetic Curie temperatures T_c are indicated by arrows.

The magnitudes of $K(T)$ at 250 K, ranging from 8 to 1 W/m K are comparable to values reported for LaMnO_3 (Refs. 5, 6) as well as YBCO.⁹ In comparison, the thermal conductivity of a good metal is much larger, e.g., Cu at room temperature is on the order of 400 W/m K. Shown in Fig. 2 is the temperature dependence of the resistivity for $(\text{Sr}, \text{Ca})\text{RuO}_3$; like the high-temperature superconducting compounds, the resistivity at and above room temperature varies linearly with T . For SrRuO_3 , the calculated mean free path is on the order of the lattice spacing, typical of “bad metals.”¹⁰ As shown in Fig. 2, a clear anomaly is seen in the resistivity at the Curie temperature, T_c .

The thermal conductivities of both SrRuO_3 and CaRuO_3 increase as the temperature decreases ($dK/dT < 0$) at higher temperatures. An Umklapp-limited peak occurs as lattice impurities dominate over phonon processes at approximately the same temperature, 60 K, followed by a drop in the thermal conductivity at low temperatures. For an electronic system, low-temperature thermal resistivity typically follows a power law given by

FIG. 2. Electrical resistivity vs temperature for $\text{Sr}_{1-x}\text{Ca}_x\text{RuO}_3$. The ferromagnetic Curie temperatures T_c are indicated by arrows.

$$W(e) = \frac{a}{T} + bT^2, \quad (1)$$

where $W(e) = 1/K(e)$, a/T represents impurity scattering, and bT^2 is due to electron-phonon scattering. At sufficiently low temperatures, the thermal conductivity then usually drops off as T . In addition, SrRuO_3 has a slope change in the thermal conductivity at the ferromagnetic ordering T_c for both the electrical and thermal conductivities. In contrast, the crystals with $x=0.25$ and $x=0.5$ do not display any anomalies in $K(T)$ at T_c even though a clear anomaly is observed in the resistivity. At high temperatures, $K(T)$ for $x=0.25$ and 0.50 behave similar to amorphous materials ($dK/dT > 0$). The Umklapp-limiting peak is not present. This is similar to behavior seen in thermal conductivities measured for certain dopings of LaMnO_3 .^{5,6} The amorphous-like behavior of the thermal conductivity reflects a reduction in the mean free path of the carriers as increasing lattice impurities or distortions decrease the electron and phonon scattering lifetimes. This is puzzling since these are high quality single crystals.

Resistivity data from $\text{Sr}_{1-x}\text{Ca}_x\text{RuO}_3$ can be used to estimate the electronic thermal conductivity using the Wiedemann-Franz law $K(e) = L_0 T / \rho$, where $L_0 = 2.4 \times 10^{-8} \text{ W}/\Omega \text{ K}^2$ is the ideal Lorenz number, and ρ is the resistivity. Using data obtained from Fig. 2, and assuming that in this region $K(\text{tot}) = K(e) + K(\text{ph})$, the phonons account for $\sim 50\%$ of the thermal conductivity. By comparison, in a good metal like Cu the phonon portion will be on the order of 5%. An estimate of the Lorenz number for SrRuO_3 has been obtained assuming the anomaly in both $\rho(T)$ and $K(T)$ is solely driven by critical scattering of the electron transport. In Fig. 3, an expanded view of $K(T)$ and $\rho(T)$ above and below T_c are shown. Assuming that contributions to the magnetic critical scattering in the vicinity of T_c are electronic in nature and the phonons only contribute a smooth temperature dependence to $K(T)$, we can estimate the Lorenz number from the following expressions:

$$K(\text{tot}) = K(\text{ph}) + \frac{LT}{\rho}, \quad (2)$$

$$\frac{dK}{dT} = \frac{dK(\text{ph})}{dT} + \frac{L}{\rho} + \frac{LT}{\rho^2} \frac{d\rho}{dT}. \quad (3)$$

Taking the limits as $T \rightarrow T_c$ from both sides, the Lorenz number for SrRuO_3 is determined to be $L = 1.63 \times 10^{-8} \text{ W}/\Omega \text{ K}^2$. This is smaller than the ideal Lorenz number, $L = 2.4 \times 10^{-8} \text{ W}/\Omega \text{ K}^2$.

To better understand the relative importance of electrons and phonons to $K(T)$, the magnetic field dependences of $K(T)$ and $\rho(T)$ have been measured. Measurements of thermal and electrical magnetoresistivities are summarized for SrRuO_3 and CaRuO_3 in Fig. 4, where $[\rho(B) - \rho(0)]/\rho(0)$ and $[W(B) - W(0)]/W(0)$ with $W = 1/K$ are shown. For SrRuO_3 , the field dependences of the electrical and thermal resistivities are both negative at higher temperatures, as the resistance is decreased due to a reduction in electronic scattering processes. As the temperature is reduced, the electrical magnetoresistivity decreases, displaying a maximum near the

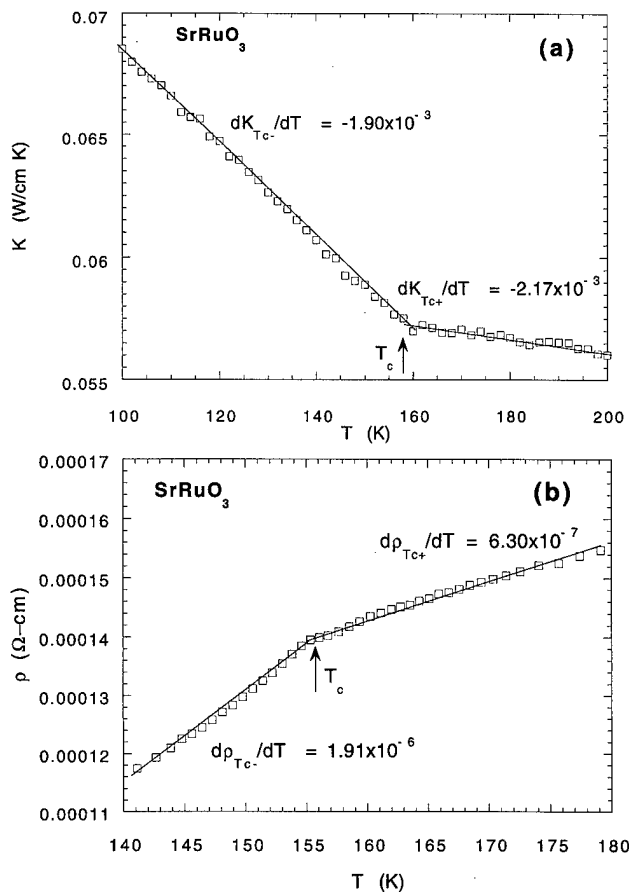

FIG. 3. (a) The slopes of K vs T above and below T_c . (b) The slopes of ρ vs T above and below T_c . These values are used to estimate a Lorenz number of $L = 1.63 \times 10^{-8}$ W/ Ω K² in SrRuO₃.

ferromagnetic transition. Such behavior is characteristic of ferromagnetic systems where the damping of the ferromagnetic fluctuations in the vicinity of T_c leads to a negative magnetoresistance peaking around T_c . However, the thermal magnetoresistance has a maximum value near the Umklapp-limiting peak, before decreasing and changing signs at lower temperatures. In CaRuO₃, the electrical magnetoresistance is small (<2%) at all temperatures, but the magnetothermal resistivity has a substantial contribution at temperatures below 60 K. This field dependence is unexpected, since there is no magnetic ordering in CaRuO₃. However, a very small percentage of doping ($\sim 1\%$) does lead to magnetic tendencies in this compound. High field magnetization data, as well as a large Pauli susceptibility term, indicate that CaRuO₃ is a strongly exchange-enhanced paramagnet, which points to the possibility of spin fluctuations contributing to scattering processes at lower temperatures.

In summary, the thermal conductivities for Sr_{1-x}Ca_xRuO₃ have been investigated as a function of field and temperature. Using the Wiedemann-Franz Law and measured resistivity, 50% of the thermal conductivity is estimated to be phononic near room temperature. An estimate of the Lorenz number has been obtained for SrRuO₃ assuming that the anomaly seen in both $\rho(T)$ and $K(T)$ is due to critical scattering of the electrons. A value smaller than the

FIG. 4. Plots of magnetoresistivity and magnetothermal resistivity at $H = 10$ T as a function of temperature. Shown are the electrical resistivity of SrRuO₃ (triangles), thermal resistivity of SrRuO₃ (diamonds) and thermal resistivity of CaRuO₃ (circles).

ideal Lorenz number is obtained, $L = 1.63$ W/ Ω K². Amorphous behavior is observed in the doped samples, and no break in the thermal conductivity is seen at the ferromagnetic onset even though a clear anomaly is seen in $\rho(T)$. Also, field dependences of the thermal resistivities of SrRuO₃ and CaRuO₃ are not consistent with the electrical resistivities, which points to an additional contribution to the magnetic behaviors in addition to electronic scattering. Evidence for magnon-phonon scattering has been investigated for SrRuO₃, and the magnetic thermal conductivity of CaRuO₃ is similar to behavior noted in other nearly magnetic systems.¹¹ Research is continuing on these systems to better determine the role of phonon, electrons, and magnons to the transport properties of these interesting systems.

Magnetization and magnetoresistivity of as-grown, oxygenated, and argon annealed single crystals of $\text{Ca}_3\text{Ru}_2\text{O}_7$ are presented for $5 < T < 300$ K and $0 < H < 7$ T. As-grown $\text{Ca}_3\text{Ru}_2\text{O}_7$ has been shown to have an antiferromagnetic metallic phase for $48 < T < 56$ K and $0 < H < 4$ T, located between the high-temperature paramagnetic metallic and the low-temperature antiferromagnetic insulating phase. Details of the field dependence of the magnetoresistance of as-grown $\text{Ca}_3\text{Ru}_2\text{O}_7$ show slight variations between the H - T metal-insulator and paramagnetic-antiferromagnetic phase boundaries as determined from magnetization and from magnetoresistance measurements, but well-characterized samples with oxygen addition or deletion show much more extensive variations. Oxygenation lowers the electrical resistivity and sustains the 6 T first-order field-induced magnetic transition for $T \ll T_M$. However, magnetization is linear through the same field region, and argon annealed samples, with decreased oxygen content, show the same linearity of the magnetization. The results underscore the importance of oxygen content in the ruthenates, in analogy with the role of oxygen content in the cuprates. © 1998 American Institute of Physics. [S0021-8979(98)33811-6]

Transition metal oxide systems with extended d -shell orbitals, particularly those of the $4d$ and $5d$ transition elements, generally show metallic conductivity and a weak non-localized magnetic moment. Transition metal oxide systems with more localized d -shell orbitals, in particular those of the $3d$ elements, tend to be more highly correlated and are often insulators with highly localized magnetic moments. Many of the transition metal oxide systems currently under intense scrutiny are exceptions to these rather general assertions, and they show anomalous properties because the electrons responsible for the moment are degenerate or nearly so with those responsible for charge transport. The transition metal oxides of ruthenium fall into this category, and at least in the material studied most extensively, SrRuO_3 , the d -electrons which give rise to localized-like magnetism are also responsible for the electrical transport, there being essentially no s -like contribution to the density of states at the Fermi surface.¹

Of the ruthenate materials studied to date, the anisotropic bilayered compound $\text{Ca}_3\text{Ru}_2\text{O}_7$ possesses the most extensive and varied array of properties.² The high-temperature effective paramagnetic moment, $2.42\mu_B/\text{Ru}$, is close to that expected for the low spin state ($S=1$) of the $4d^4$ Ru configuration, $2.83\mu_B/\text{Ru}$. To date all work has been reported on as-grown single crystals of $\text{Ca}_3\text{Ru}_2\text{O}_7$,² and this report focuses on more detailed measurements of the magnetic and transport properties of as-grown $\text{Ca}_3\text{Ru}_2\text{O}_7$ but also reports preliminary data for oxygen annealed (oxygen-rich) and argon annealed (oxygen-poor) samples. Details of sample preparation of the as-grown single crystals are given elsewhere.² Some of the materials in this study were annealed in high purity oxygen for periods of up to two days to increase the oxygen content and others in high purity argon for the same period in order to deplete the oxygen content. In

all the samples studied the Ca/Ru ratio was maintained according to analysis determined with a scanning electron microscope using electron dispersive energy analysis. Annealing times in excess of two days caused the samples to lose their as-grown shiny appearance and gave spurious electrical conductivity.

In Ref. 2, we presented the magnetic and transport properties of as-grown single crystal $\text{Ca}_3\text{Ru}_2\text{O}_7$ for the purpose of describing an antiferromagnetic metallic (AFM) phase which spans the temperature range, $48 \leq T \leq 56$ K, between the high temperature, $T > T_N = 56$ K, paramagnetic metallic (PMM), and low temperature, $T < T_M = 48$ K, antiferromagnetic insulating (AFI) phase. The transition from PMM to AFM is second order, the transition from AFM to AFI being first order. Detailed electrical resistivity versus temperature data, $\rho(T)$, showing both transitions is shown in Fig. 1 for several values of the applied magnetic field, where the field is along the "easy" magnetocrystalline axis $[110]$. The inset shows $\rho(T)$ for $H=0$ over a more extensive temperature range. Several features of the data of Fig. 1 and the inset should be noted: (1) The resistivity is "metallic," i.e., $d\rho/dT > 0$, for all $T > T_M$ but it has a very large magnitude, even in well-characterized single-crystal samples. This alone probably puts $\text{Ca}_3\text{Ru}_2\text{O}_7$ in the "bad metal" category, namely, $k_F\lambda \approx O(1)$, where λ is the quasiparticle mean free path calculated if Boltzmann transport were to apply.³ (2) A puzzling aspect of $\rho(T)$ for $T > T_M$ is the isotropy: there is practically no detectable variation in the $\rho(T)$ for layered $\text{Ca}_3\text{Ru}_2\text{O}_7$ for current along the $[100]$, $[010]$, or $[001]$ directions, though there are large variations in the paramagnetic regime of a sister compound, $\text{Sr}_3\text{Ru}_3\text{O}_7$,⁴ which undergoes ferromagnetic transitions below about 105 K. (3) At $T = T_M$, $\rho(T)$ rises abruptly (and with slight thermal hysteresis) but does not attain large values as in the case of the canonical metal in-

FIG. 1. Detail of the electrical resistivity vs temperature in the region of the two magnetic transitions in $\text{Ca}_3\text{Ru}_2\text{O}_7$ taken at several external magnetic fields along the "easy" magnetocrystalline axis, $[110]$. The arrows denote the Neel temperature for the various fields. The inset shows electrical resistivity at zero field over an extended temperature range.

sulator transition material, V_2O_3 .⁵ For $T < T_M$, $\rho(T)$ of $\text{Ca}_3\text{Ru}_2\text{O}_7$ shows large anisotropy (factors of $O(2)$ between current parallel to $[100]$ vs $[001]$), which suggests a structural change or perhaps a shift in the conductivity to lower dimensionality at T_M .

One feature common to all as-grown samples of $\text{Ca}_3\text{Ru}_2\text{O}_7$ is the very close coupling of spin and charge system at low temperatures as evidenced by their respective behavior at the several zero and high field transitions. Most recently, data taken in pulsed magnetic fields demonstrated a AFI to PMM transition for $H||[001]$, the "hard" magnetocrystalline axis: Both isothermal $M(H)$ and $\rho(H)$ for $T \ll T_M$ show a first-order-like transition at $H = 37$ T.⁶ For $H||[110]$, the "easy" axis (see data of Fig. 1), the transition occurs at much lower fields, 6 T. The pulsed field data demonstrate this close spin-charge coupling persists even in fields to 37 T.

The data of Fig. 1 show for the first time the magnetic field dependence of the AFM transition determined from $\rho(H, T)$ with $H||[110]$. The break in the resistivity curve at $T_N = 56$ K is apparent in this figure. Normally, this decrease could be associated with a Fisher-Langer⁷ type anomaly, i.e., spin flip scattering decreases for $T < T_N$, thereby decreasing $\rho(T)$. However, that theory addresses s -wave scattering at localized magnetic sites, which does not at all resemble the situation in the ruthenates because of the absence of s -electrons at the Fermi surface. Nevertheless, the resistive anomaly is consistent with the loss of spin flip scattering. The $M-I$ transition becomes more rounded with increasing field, and the PMM-AFM transition is initially suppressed with field and then becomes more rounded. The field appears to have no effect on the $M-I$ transition up to 4 T, although there is some broadening of the onset, and the line of $M-I$ transitions terminates at a critical point at $H = 4$ T and $T = 48$ K. (The data of Fig. 1 are from a different sample than presented in Ref. 2.) The apparent transition at about 52 K for $H = 5$ T may reflect some combination of field-induced magnetic and structural changes over a wider temperature range.

FIG. 2. Magnetization divided by applied field for $\text{Ca}_3\text{Ru}_2\text{O}_7$ along $[110]$ vs temperature in the vicinity of two magnetic transitions. The inset shows an expanded temperature range for 0.5 T applied field.

In Fig. 2 we show the temperature dependence of the magnetization, $M(H, T)$, for several applied fields with $H||[110]$, and as in Fig. 1, the data are shown for the vicinity of the PMM-AFM and AFM-AFI transitions. The inset shows the low field susceptibility data over a much wider temperature range, showing the magnetic ordering temperature and the subsequent reduction of the magnetization below the $M-I$ transition. The Neel temperature, T_N , de-

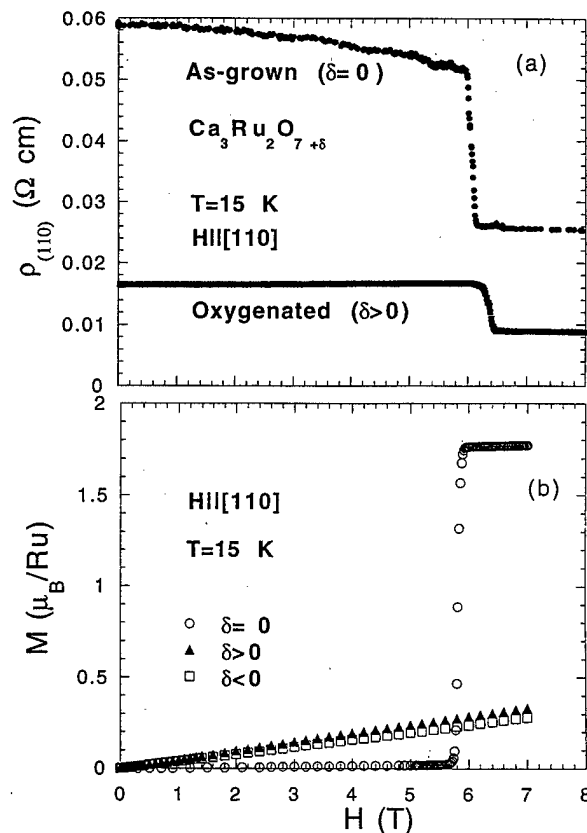

FIG. 3. (a) Electrical resistivity vs field along the easy axis for as-grown and oxygenated single crystals of $\text{Ca}_3\text{Ru}_2\text{O}_7$ showing transition from the antiferromagnetic insulating to the paramagnetic metallic phase. (b) Magnetization vs field for as-grown, oxygenated, and oxygen depleted samples in the vicinity of the field-induced phase transition of (a).

creases uniformly with field, in accordance with the resistivity data of Fig. 1. At low temperatures, the field-induced $M-I$ transition is tightly coupled to the metamagnetic transition, indicating the charge and spin mechanisms are intimately related. This field-induced metamagnetic transition results from strong anisotropic forces dominating the exchange forces, but near T_N the anisotropic forces weaken, and a two-step metamagnetism appears.² The $M-I$ transition temperature, as measured by the sharp $M(H, T_M)$ drop, decreases with increasing field and becomes more rounded. This is further evidence for a weakening of the anisotropic forces near T_N . Yet, the $\rho(H, T)$ measurements of Fig. 1 indicate the $M-I$ transition appears to be field independent, contrary to Fig. 2, thus suggesting that the charges and spins decouple in the vicinity of T_N .

Figure 3 illustrates some rather dramatic differences in magnetization and transport data obtained from as-grown samples vs. annealed samples. The as-grown data shown are the same as those in Ref. 2, but many other measurements on as-grown single crystals show nearly identical field-induced transitions. All data were taken at $T=15\text{ K} \ll T_M$ and illustrate the first-order character of the transition from the AFI to the PMM phase. Whereas the field-induced metamagnetic transition at $H=6\text{ T}$ can be seen from both resistivity and magnetization data for the as-grown crystals, the latter is absent entirely from the oxygen-rich and oxygen-depleted crystals. The drop in $\rho(T, H=6\text{ T})$ is as precipitous at the transition field as in the as-grown crystal, decreasing to about 50% of the zero field value.

The data of Fig. 3 suggest a decoupling of the magnetic and transport properties in $\text{Ca}_3\text{Ru}_2\text{O}_7$ with altered oxygen content. Preliminary measurements indicate the following consistencies: (1) The $M-I$ transition temperature never varies from $T_M=48\text{ K}$, as determined from $\rho(T)$ measurements, regardless of the type of annealing procedure (except for highly oxygenated but not well characterized samples).

(2) Oxygen-rich samples show generally higher conductivity, perhaps due to hole-like carrier doping, and oxygen-poor samples (argon annealed) show lower (sometimes nonmetallic) conductivity than as-grown crystals. (3) For both cases shown in Fig. 3 the field-induced metamagnetic transition is seen for resistive measurements but not magnetic measurements, at least to 7 T. The data suggest the "easy" axis may have shifted from $[110]$, though the evidence from resistivity measurements suggests it has not. It is interesting that the susceptibility represented by M/H for non as-grown samples is the same as the susceptibility of as-grown samples for the field along the "hard" $[001]$ axis, suggesting a major shift of the easy axis as a result of oxygen content (A shift in the easy axis of magnetization was found in $\text{Sr}_{1-x}\text{Ca}_x\text{RuO}_3$ for $0.2 < x < 0.5$).⁸)

Future high field experiments will attempt to quantify the role of oxygen content in magnetocrystalline anisotropy in the ruthenates. In general, we believe that for the ruthenates, oxygen content will be as important parameter in predicting the physical properties as it is for the cuprates.

Anisotropic Magnetoresistance and Granular GMR

Thomas McGuire, Chairman

Anisotropic magnetotransport properties of epitaxial thin films of conductive ferromagnetic oxide SrRuO_3

R. A. Rao, D. B. Kacedon, and C. B. Eom^{a)}

Department of Mechanical Engineering and Materials Science, Duke University, Durham, North Carolina 27708

We have studied the crystallographic domain structure dependent anisotropy in the magnetotransport properties of epitaxial thin films of the conductive ferromagnetic oxide SrRuO_3 . Single domain SrRuO_3 thin films on miscut (001) SrTiO_3 substrates exhibit a strong anisotropy in magnetization and magnetoresistance that reflects the inherent magnetocrystalline anisotropy of the material. In contrast, the SrRuO_3 thin film on (001) LaAlO_3 substrate shows identical magnetization and magnetotransport properties in two orthogonal directions on the film due to the presence of 90° domains in the plane. For both films, large negative magnetoresistance effects ($\sim 10\%$) are observed when the applied magnetic field is parallel to the current due to the suppression of spin fluctuations near T_c and the anisotropic magnetoresistance effect at low temperatures. © 1998 American Institute of Physics. [S0021-8979(98)31711-9]

Since the discovery of colossal magnetoresistance (CMR) in doped perovskite manganite thin films,¹ there has been a great deal of interest in the magnetoresistance of perovskite magnetic oxide thin films. Among the many perovskite magnetic oxides SrRuO_3 is especially attractive, since it is a rare case of $4d$ itinerant ferromagnetism ($T_c \sim 160$ K) with a GdFeO_3 -type pseudocubic perovskite structure and a bulk lattice parameter of 3.93 \AA .^{2,3} This material exhibits strong magnetocrystalline anisotropy in single crystal bulk³ and single domain thin film⁴ samples. It is also structurally and chemically similar to the LaMnO_3 -based CMR materials. As in CMR materials, magnetic ordering decreases electrical resistivity in SrRuO_3 rendering it attractive for magnetotransport studies.⁵

The successful growth of single crystal SrRuO_3 thin films on miscut SrTiO_3 substrates⁶ allows us to study the intrinsic anisotropic magnetotransport properties of SrRuO_3 . Recently, we have controlled the growth mechanisms⁷ and domain structure⁸ of SrRuO_3 thin films by using miscut substrates. In this article, we report on the magnetization and magnetotransport properties of epitaxial SrRuO_3 thin films with different crystallographic domain structures.

The SrRuO_3 thin films were deposited from a 2 in. diam stoichiometric composite target using a 90° off-axis sputtering technique^{9,10} on a vicinal (001) SrTiO_3 substrate miscut by 2° towards the in-plane [010] axis and an exact (001) LaAlO_3 substrate. The thickness of the films is about 3000 \AA .

The film on 2° miscut (001) SrTiO_3 substrate grew by step flow due to the presence of a periodic step structure on the substrate.⁷ This film has a purely (110) texture normal to the substrate. All the crystallographic planes and direc-

tions for SrRuO_3 referred to in this work are based on the orthorhombic unit cell. As the miscut direction is close to the [010] direction of the substrate, the one directional step flow leads to a single domain film with an in-plane epitaxial arrangement of $\text{SrRuO}_3[\bar{1}10]/\text{SrTiO}_3[010]$ and $\text{SrRuO}_3[001]/\text{SrTiO}_3[100]$.⁸ Furthermore, due to the small lattice mismatch between SrRuO_3 and SrTiO_3 this film has a coherent growth resulting in a strained lattice with in-plane and out-of-plane lattice parameters of 3.90 and 3.96 \AA , respectively.

The film on LaAlO_3 substrate has a three dimensional island growth mechanism⁷ due to the large lattice mismatch with the substrate. Therefore, this film has a strain-free lattice with both in-plane and out-of-plane lattice parameters the same as that of the bulk material (3.93 \AA). The out-of-plane film texture is a mixture of (110) and (001) normal to the substrate.

The influence of the domain structure on the magnetization of the films was studied with a superconducting quantum interference device (SQUID) magnetometer. The samples were cooled in a magnetic field of 0.05 T applied parallel to the film surface. Magnetization measurements on the single domain film showed an anisotropic behavior with the in-plane $[\bar{1}10]$ direction being the easier axis for magnetization compared to the [001] direction, which is in agreement with previously reported results. Accordingly, this film showed a fully saturated magnetization at low temperatures ($\sim 5 \text{ K}$), when the field is applied along the $[\bar{1}10]$ direction, as shown in Fig. 1(a). However, an unsaturated and lower magnetization ($\sim 65\%$ of the value in the $[\bar{1}10]$ direction) is obtained when the field is in the [001] direction. In contrast, the film on LaAlO_3 shows identical unsaturated magnetization when the field is applied along any of the two orthogonal directions on the film surface due the presence of 90° domains in the plane of the film, as shown in Fig. 1(b).

FIG. 1. Temperature dependence of magnetization of (a) single domain SrRuO₃ thin film on miscut SrTiO₃ and (b) multidomain SrRuO₃ film on (001) LaAlO₃ substrate. The inset shows the field direction with respect to the crystallographic directions of the film and substrate denoted by the subscripts *F* and *S*, respectively.

Magnetoresistance (MR) measurements were performed on these films using an Oxford Instruments MAGLAB 2000™ materials characterization system. For the single domain SrRuO₃ thin film, the resistivity was measured in four orientations of the *J* (current density) and *H* (applied field) directions with respect to the in-plane $\bar{1}10$ and 001 directions of the film (i.e., $J \parallel H \parallel \bar{1}10$; $J \parallel H \parallel 001$; $J \perp H$, $J \parallel 001$; and $J \parallel \bar{1}10$). In contrast, for the film on an exact (001) LaAlO₃ substrate, the resistivity was measured along the 010 and 100 directions of the LaAlO₃ substrate in two orientations ($J \parallel H$ and $J \perp H$) because of the equivalence of the two orthogonal directions. The temperature dependence of resistivity was measured by zero-field cooling (ZFC) and field warming.

The temperature dependence of resistivity for both the films in zero applied field shows the characteristic change of slope at the Curie temperature (*T_c*) signifying a ferromagnetic phase transition. Above *T_c* the resistivity increases linearly with temperature and is expected to continue without saturation.¹¹ The *T_c* of the film on SrTiO₃ (~120 K) is also significantly lower than that for the film on LaAlO₃ substrate (*T_c* ~ 155 K). This *T_c* suppression in the films on SrTiO₃ substrate is believed to be due partly to the coherent growth induced lattice strain in these films.¹² Furthermore, it is believed that this film might be a little deficient in Ru, which could also contribute to the *T_c* suppression.

The magnetoresistance was calculated as: $MR = [\rho(H) - \rho(0)]/\rho(0)$, where $\rho(H)$ and $\rho(0)$ are the resistivity at a field *H* and at zero field, respectively. The largest MR among all four combinations of *J* and *H* directions is observed at low temperatures, when the current and field are parallel to

FIG. 2. The negative AMR vs temperature for a single domain SrRuO₃ film on 2° miscut (001) SrTiO₃ substrate toward the 010 direction at applied fields of 4 and 8 T with $J \parallel \bar{1}10$.

the $\bar{1}10$ direction.¹³ We believe that this is due to the $\bar{1}10$ direction being the easier axis for magnetization compared to the 001 direction. The spins are more easily aligned in the $\bar{1}10$ direction which accounts for the larger change in resistivity due to the magnetic field.

A large negative MR is observed at temperatures just below *T_c* in all orientations of the current and field which has already been attributed to the suppression of spin fluctuations.¹⁴ Furthermore, the negative MR is larger when the applied field is parallel to the current, especially at low temperatures. This is due to the anisotropic magnetoresistance (AMR) effect. The AMR effect is the change in angle between the magnetization and current because of magnetization rotation observed at high fields that are smaller than the anisotropy field. Such an AMR effect has been observed in single domain SrRuO₃ thin films at a field of 6 T and is found to increase as the temperature is lowered below *T_c*.¹⁵

Figure 2 shows the negative AMR as a function of temperature at two different values of applied field for the single domain film with current along the miscut direction. The AMR is measured as the ratio of change in resistivity to the average resistivity as shown below:

$$\frac{\Delta \rho}{\rho_{av}} = \frac{3(\rho_{\parallel} - \rho_{\perp})}{(\rho_{\parallel} + 2\rho_{\perp})}, \quad (1)$$

where ρ_{\parallel} and ρ_{\perp} are resistivities with *H* parallel and perpendicular to the current direction. The AMR is unusual in sign since usually ρ_{\perp} is less than ρ_{\parallel} . The magnitude of the AMR is ~8% at low temperatures and high fields. Clearly, the AMR increases as the field is increased and the temperature is lowered. As the easy axis of SrRuO₃ lies in the (001) plane making an angle of 30°–45° with respect to the $\bar{1}10$ direction,⁴ complete orientation of *M* along the applied field direction does not take place when the field is applied in the (110) plane. Therefore, as the field is increased the angle between *M* and the current changes leading to the AMR effect. It has been shown that the Lorentz force component for $H \perp J$ in these films is negligible.¹⁴ Furthermore, if Lorentz force were to dominate, a positive MR should have been seen above *T_c* for $H \perp J$. However, all films show negligible MR above *T_c* which suggests that the difference between $H \parallel J$ and $H \perp J$ is primarily due to the AMR effect.

The field dependence of the magnetoresistance was also measured in the four combinations of *J* and *H* directions.

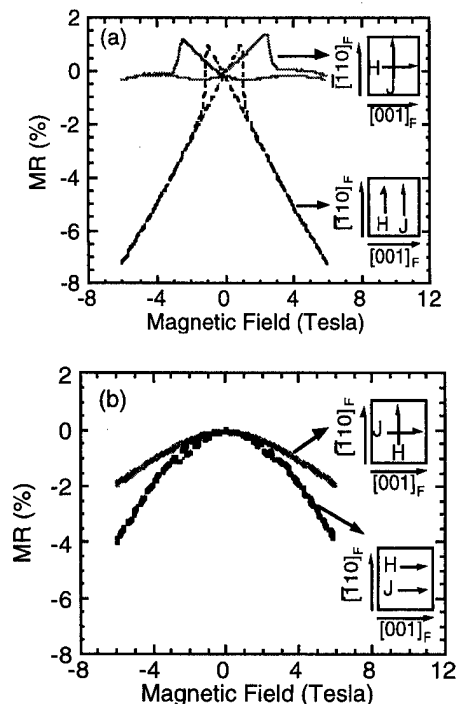

FIG. 3. MR vs field of a SrRuO₃ film on a 2° miscut SrTiO₃ substrate with (a) $J \parallel [110]$ and (b) $J \parallel [001]$.

The samples were heated to above T_c in zero field between successive MR versus field measurements, in order to erase any hysteresis effects. Figures 3(a) and 3(b) compare the hysteresis in the MR versus field data at 5 K for the single domain SrRuO₃ thin film with the current along the $[110]$ and $[001]$ direction. As the film is single domain, the magnetocrystalline anisotropy of SrRuO₃, which is attributed to the large spin-orbit coupling of Ru, contributes to a strong anisotropy in the MR behavior seen in Fig. 3. The hysteresis effect itself is related to the magnetization hysteresis. The peak in the MR hysteresis corresponds to the coercive field and the point of overlap between the forward and backward sweeps of the field corresponds to the saturation field. As the applied field is increased beyond saturation, the magnetization of the sample does not change significantly, but magnetization rotation occurs contributing to a larger negative MR when $J \parallel H$ due to the AMR effect.

The magnetoresistance properties of the multi domain film on LaAlO₃ were also measured. In contrast to the single domain film, the resistivity of this film has an additional contribution from the crystallographic domain boundaries due to the incoherent three dimensional island growth. The temperature dependence of MR for the film on LaAlO₃ showed features similar to that of single domain film on miscut SrTiO₃. A sharp increase in MR at T_c and larger MR at low temperatures are observed when the field and current are parallel.

The field dependence of MR shows some differences compared to the single domain film, as seen in Fig. 4. The MR at 5 K is shown in two orthogonal directions with $J \parallel H$ and $J \perp H$. When the sample was rotated by 90° the MR behavior obtained was identical due to the equivalence of the two orthogonal directions within the plane. The grain size of

FIG. 4. MR vs field of a SrRuO₃ film on an exact (001) LaAlO₃ substrate with $J \parallel H$ and $J \perp H$.

these films, as observed from scanning tunneling microscopy images⁷ and the magnetic domain wall spacing of similar films observed by Lorentz microscopy imaging,¹⁶ are comparable (~ 2000 Å). Therefore, it is believed that the film on LaAlO₃ does not have any magnetic domain walls. The crystallographic domain boundaries in this film act as magnetic boundaries as well and the change in relative orientation of the magnetization of adjacent crystallographic domains contributes to the hysteresis.

The authors would like to thank M. L. Stutzman for patterning the samples, M. Lee for SQUID measurements, and L. Klein and Q. Gan for helpful discussions. Results of resistivity and Hall effect measurements in $\text{La}_{1-x}\text{Ca}_x\text{CoO}_3$ ($0.1 \leq x \leq 0.5$) epitaxial films and ceramics are presented. The spontaneous Hall effect in $\text{La}_{1-x}\text{Ca}_x\text{CoO}_3$ (LCCO) is observed for ferromagnetic samples with $x \geq 0.2$. The Hall effect is largest near the magnetic percolation threshold $x = 0.2$. For $x = 0.2$, the low-field slope of the Hall resistivity, $\rho_{xy}/(\mu_0 H)$, attains a large value of $2 \times 10^{-6} \text{ m}^3/\text{C}$ below the Curie temperature T_c , which may be applied to sensitive low-field detection. Except near the magnetic percolation threshold, the longitudinal resistivity of LCCO decreases with increasing field at all temperatures. Anomalous temperature-dependent magnetoresistance occurs in the sample with $x = 0.2$, which may be associated with the spin-state transition in LCCO. © 1998 American Institute of Physics. [S0021-8979(98)26211-6]

I. INTRODUCTION

The perovskite cobaltite oxide $\text{La}_{1-x}\text{Ca}_x\text{CoO}_3$ (LCCO) is ferromagnetic for $x > 0.15$, with the Curie temperature increasing up to $T_c \approx 180 \text{ K}$ for $x = 0.3$ – 0.5 ¹ (see Fig. 1, upper inset). Substitution of divalent Ca for trivalent La in the parent compound LaCoO_3 results in mixed valency of Co ions ($\text{Co}^{3+}/\text{Co}^{4+}$), and chemically doped holes induce ferromagnetism via the double-exchange interaction.^{2–4} Both the trivalent and tetravalent cobalt ions are known to exist in multiple spin configurations. For instance, low- and high-spin states for trivalent cobalt ions have the electronic configurations of $t_{2g}^6 e_g^0$ (Co^{III}) and $t_{2g}^4 e_g^2$ (Co^{3+}), with spin $S = 0$ and 2, correspondingly.^{5,6} In LaCoO_3 , the crystal-field splitting energy is larger than the Hund's energy, and the trivalent Co ions are in the low-spin state at low temperatures. Divalent Ca ions in $\text{La}_{1-x}\text{Ca}_x\text{CoO}_3$ polarize the oxygen p electrons and stabilize the high-spin configuration of trivalent Co ions because of the reduced crystal-field effect. As a result, magnetic clusters are formed near each divalent atom. With the increasing doping concentration, the clusters reach magnetic and conducting percolation threshold. A similar system, $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$, is found to have metallic electrical conduction for $0.3 \leq x \leq 0.5$, with "hole-poor", lower-spin matrix interpenetrating the metallic "hole-rich", higher-spin regions.^{5,6} In this work, we report the observations of a giant ferromagnetic Hall effect and magnetoresistance in LCCO. The possible physical origin of these phenomena is discussed in the context of magnetic clusters and spin transitions due to the multiple spin configurations of the cobaltites.

II. EXPERIMENT

The transport properties are studied in LCCO epitaxial films ($x = 0.2, 0.3$, and 0.5) and in a LCCO $x = 0.1$ ceramic

sample. The films, $(2\text{--}5) \text{ mm} \times (2\text{--}5) \text{ mm} \times (100\text{--}300) \text{ nm}$ in size, are grown by pulsed laser deposition using stoichiometric targets of LCCO, in 100 mTorr of oxygen. The temperature of the LaAlO_3 substrates is 700°C . The growth is followed by annealing in 1 atm oxygen at 900°C for 10 h, and the epitaxy of the films is confirmed by x-ray rocking curves. The results for the $x = 0.5$ samples⁷ are very similar to those for the $x = 0.3$ sample and are not shown here. The ceramic sample, $6.1 \text{ mm} \times 2.8 \text{ mm} \times 1.7 \text{ mm}$ in size, is cut from the LCCO target with $x = 0.1$. The magnetic field is applied perpendicular to the plane of the largest dimensions. Details of transport measurements are given in Ref. 7.

III. RESULTS

Figure 1 shows the temperature (T) dependence of the electrical resistivity ρ in zero magnetic field. The sample

FIG. 2. (Upper panel) The magnetic field dependences of the longitudinal resistivity for $x=0.1$, 0.2 , and 0.3 . The temperature is indicated near each curve. Solid lines are guides to the eye.

with $x=0.3$ exhibits metalliclike resistivity. Below T_c , increasing magnetic order with decreasing temperature decreases carrier scattering and therefore results in a large decrease in the resistivity on cooling through T_c (Fig. 1, lower inset). The resistivity of the samples with $x=0.2$ and 0.1 has semiconductinglike behavior (Fig. 1, main panel), which has been attributed to trapping of holes at the divalent doping ions.⁵

The magnetic field (H) dependence of the resistivity is depicted in Fig. 2. The origin of the negative magnetoresistance for $x=0.3$ can be understood in terms of conventional behavior for metallic ferromagnets, where the magnetoresistivity is due to the suppression of the spin-disorder scattering, which is strongest near the transition temperature, see Fig. 2, bottom panel.

For the ceramic $x=0.1$ sample (Fig. 2, top panel), the magnetoresistance is also negative, and at low temperatures attains relatively larger values (up to 25%) than those of the metallic samples. Unlike samples with high concentration of the Ca atoms, which demonstrate bulk ferromagnetism, the $x=0.1$ sample consists of isolated clusters containing Co^{3+} and tetravalent cobalt ions. These clusters are localized at the Ca ions at low temperatures. The electrical conduction occurs via the hopping motion of holes in the insulating matrix of low-spin, trivalent Co^{III} ions. Each hopping process consists of transferring the tetravalent configuration $[\text{Co}^{\text{IV}} (S=1/2) \text{ or } \text{Co}^{4+} (S=5/2)]$ from one Co ion to another, accompanied by transforming of the neighboring Co^{III} ions into Co^{3+} ions.⁵ With increasing temperature, the ratio of Co^{3+} to Co^{III} ions in the matrix increases, facilitating the hopping process and increasing the conductivity. On the other hand, the presence of an external magnetic field helps aligning the spins of Co^{3+} and $\text{Co}^{4+}(\text{Co}^{\text{IV}})$ ions, thereby increasing the hopping rate and resulting in negative magnetoresistivity. With increasing temperature, the correlations between the spins of Co^{3+} and $\text{Co}^{4+}(\text{Co}^{\text{IV}})$ ions become weaker, therefore larger fields are required to align the spins, and the magnetoresistance decreases (Fig. 2, top panel). We note that the magnetoresistance data on LCCO with $x=0.1$ and 0.3 are consistent with those on $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$ with the same doping levels.⁸

On the other hand, the LCCO sample with $x=0.2$ exhibits an anomalous magnetoresistance behavior (Fig. 2, middle panel), which has not been seen in $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$. The relative change of the resistivity with the magnetic field $[\rho(H) - \rho(0)]/\rho(0)$ in LCCO with $x=0.2$ is of the order of 1%, smaller than that for $x=0.3$ (Fig. 2, bottom panel). At high temperatures ($T \gtrsim 120$ K), the magnetoresistance is negative over the whole field range. At lower temperatures, the resistivity as a function of the increasing magnetic field exhibits a nonmonotonic behavior (Fig. 2, middle panel): the initial decrease at small fields is followed by an increase at larger fields. This positive upturn contribution to the resistivity at high fields increases as the temperature is lowered (compare the isotherms at $T=112.7$, 101.4 , and 91.7 K in Fig. 2, middle panel). However, when the temperature decreases further, the negative contribution grows substantially, and the positive upturn in the ρ -vs- H curves becomes less pronounced. (See the isotherm at $T=65.7$ K in Fig. 2, middle panel.) The complexity of the magnetoresistivity behavior in LCCO with $x=0.2$ may be related to the closeness of T_c to the temperature where the $\text{Co}^{3+}/\text{Co}^{\text{III}}$ ratio in the intercluster matrix reaches 50:50 (≈ 110 K, according to Ref. 5). This novel behavior in the magnetoresistance of LCCO awaits further theoretical investigations. We also note that the occurrence of the nonmonotonic field dependence of the resistivity coincides with the temperature interval in which the giant spontaneous Hall effect is observed. (See Ref. 7, Fig. 3, and the discussion below.)

Figure 3 is a representative result of the Hall effect measurements on LCCO with $x=0.2$. In our previous work,⁷ we have demonstrated that the Hall resistivity in LCCO for $0.2 \leq x \leq 0.5$ is proportional to the magnetization M : $\rho_{xy}(H, T) = R_s(T)[\mu_0 M(H, T)]$, where R_s is the spontaneous Hall co-

FIG. 3. Top panel: The Hall resistivity vs magnetic field for a $x=0.2$ epitaxial film sample. The temperature is indicated near each curve in Kelvins. Note a very steep rise of ρ_{xy} at low fields and at $T < T_c \approx 110 \text{ K}$. Bottom panel: The initial slope of the ρ_{xy} -vs- H curves as a function of temperature below $T_c \approx 110 \text{ K}$ for a $x=0.2$ epitaxial film sample. Inset: ρ_{xy} -vs- H at low fields for the same sample at $T=97.8 \text{ K}$.

efficient, and μ_0 is the permeability of vacuum. The spontaneous Hall coefficient in LCCO peaks nearest the transition temperature, with $R_s(T_c) \approx 0.25 \times 10^{-6} \text{ m}^3/\text{C}$ for $x=0.3$ and 0.5 and $1.35 \times 10^{-6} \text{ m}^3/\text{C}$ for $x=0.2$. The latter value is the largest for known ferromagnetic metals.⁷ For $x=0.1$, no Hall effect signal can be detected within our instrumental resolution. As illustrated in Fig. 3, the ρ_{xy} -vs- H curves for $x=0.2$ becomes progressively more nonlinear as the temperature is decreased in the paramagnetic state above $T_c \approx 110 \text{ K}$. In the ferromagnetic state, the Hall resistivity as a function of H is found to be hysteretic.⁷ If the sample is cooled in $H=0$, the Hall resistivity at $T < T_c$ shows a very sharp rise with increasing magnetic field, consistent with alignment of magnetic domains. We investigate this initial increase of $\rho_{xy}(H)$ by using a small copper coil to supply small fields up to $\pm 30 \times 10^{-4} \text{ T}$ (Fig. 3, bottom panel, inset). Within this magnetic field range, the Hall resistivity is linear with field and is reversible. The temperature dependence of the slope $\rho_{xy}/(\mu_0 H)$ is shown in the main panel of Fig. 3. (We note that $\rho_{xy}/(\mu_0 H)$ should not be confused with R_s : $\rho_{xy}/(\mu_0 H) = R_s M/H = R_s \chi$, where χ is the susceptibility.) The slope increases with the increasing temperature,

passes through a maximum $\rho_{xy}/(\mu_0 H) \approx 2 \times 10^{-6} \text{ m}^3/\text{C}$ at $T \approx 97 \text{ K}$ and drops to $5 \times 10^{-8} \text{ m}^3/\text{C}$ at $T=110 \text{ K}$. (The latter value is inferred from measurements over a larger field range.) The peaking behavior of $\rho_{xy}/(\mu_0 H)$ -vs- T in the ferromagnetic state is due to the decreasing susceptibility and increasing spontaneous Hall coefficient R_s with the increasing temperature.

In order to appreciate the large magnitude of the slope $\rho_{xy}/(\mu_0 H)$ in LCCO with $x=0.2$, we estimate the "effective" carrier density n , had the Hall effect in LCCO been entirely due to the Lorentz force rather than the magnetization. Using $\rho_{xy}/(\mu_0 H) = 1/(ne)$, where e is the electron charge, we obtain a small value $n = 3 \times 10^{24} \text{ m}^{-3}$, comparable to that in sensitive semiconducting Hall-effect magnetometers.

The spontaneous Hall effect in magnetic materials is generally associated with the spin-orbit interaction.^{9,10} In LCCO, the spin-orbit interaction in the ferromagnetic state may be further enhanced at the boundaries between the low-spin, low-conduction and the high-spin, high-conduction regions.

In summary, the $\text{La}_{1-x}\text{Ca}_x\text{CoO}_3$ system exhibits novel behavior in the magnetoresistance for $x=0.2$ and a very large spontaneous Hall effect at $x \geq 0.2$. These phenomena may be attributed to a magnetism associated with the coexistence of multiple spin configurations in the cobaltites. On the practical side, our finding of the giant Hall effect in these cobaltites appears promising for applications to sensitive low-field magnetometers.

Giant magnetoresistance in granular CuFeNi alloys

C. S. Martins, H. R. Rechenberg, and F. P. Missell^{a)}

Instituto de Física, Universidade de São Paulo, C.P. 66318, 05315-970 São Paulo, S. P., Brazil

Giant magnetoresistance (MR) was studied in alloys of composition $\text{Cu}_{80}\text{Fe}_{10}\text{Ni}_{10}$, $\text{Cu}_{80}\text{Fe}_{15}\text{Ni}_5$, $\text{Cu}_{80}\text{Fe}_5\text{Ni}_{15}$, and $\text{Cu}_{80}\text{Fe}_{20}$, produced by melt spinning and annealed in the temperature range 300–600 °C. Materials were characterized by Mössbauer spectroscopy at several temperatures. At both 78 and 300 K, spectra for all CuFeNi compositions showed a singlet associated with superparamagnetic Fe nanoparticles, but at 4.2 K the sextet characteristic of ferromagnetic Fe was visible. From the hyperfine field reduction we estimated the radius of the Fe particles. Magnetization data for $\text{Cu}_{80}\text{Fe}_{10}\text{Ni}_{10}$ at 300 K were compared with a model which features a log-normal distribution of noninteracting superparamagnetic particles. Thus the mean magnetic moment and the particle density were determined. The magnetoresistance ratio MR was compared to a model which considers bulk and interface scattering. © 1998 American Institute of Physics.

[S0021-8979(98)26311-0]

I. INTRODUCTION

After the discovery of giant magnetoresistance (GMR) in granular solids,^{1,2} it has become increasingly clear that the size distribution of the magnetic nanoparticles plays an important role in the phenomenon. For a random distribution of noninteracting moments of the same magnitude, the magnetoresistance ratio $\text{MR} = [\rho(H) - \rho(H=0)]/\rho(H=0)$ should be a quadratic function³ of the relative magnetization M/M_s . However, many granular systems do not follow the expected quadratic behavior and various explanations have been proposed for this. Some consider the role of magnetic interactions, while others refer to the distribution of magnetic particles. In any case, a careful consideration of this problem should furnish important insights into magnetotransport in granular solids.⁴

In the present paper we determined GMR in granular $\text{Cu}_{80}(\text{Fe}, \text{Ni})_{20}$ alloys.^{5–7} The magnetoresistance ratio MR and the relative magnetization M/M_s were studied in terms of a model which employs a log-normal distribution of noninteracting superparamagnetic particles. Mössbauer spectroscopy furnished additional information about the size of the magnetic nanoparticles.

II. EXPERIMENT

Alloys of composition $\text{Cu}_{80}\text{Fe}_{10}\text{Ni}_{10}$, $\text{Cu}_{80}\text{Fe}_{15}\text{Ni}_5$, $\text{Cu}_{80}\text{Fe}_5\text{Ni}_{15}$, and $\text{Cu}_{80}\text{Fe}_{20}$ were melt spun on a copper wheel in a He atmosphere at wheel speeds ≈ 40 m/s. Compositions reported here are in atomic percent, in contrast with Refs. 5–7 where weight percent was used. The resulting ribbons, about 1 mm wide and 30 μm thick, were then annealed in an Ar atmosphere at various temperatures in the range 300–600 °C to maximize the magnetoresistance.

Magnetization measurements were made with a vibrating sample magnetometer (VSM) mounted on a 90 kOe superconducting solenoid. Magnetoresistance was measured with an ac bridge with the magnetic field applied in the rib-

bon plane. Some measurements of the anisotropic magnetoresistance (AMR) were made in fields up to 20 kOe. For $\text{Cu}_{80}\text{Fe}_{10}\text{Ni}_{10}$, the AMR was found to be on the order of 0.5% at 300 K. A standard, constant acceleration spectrometer with a $^{57}\text{CoRh}$ source was used for the Mössbauer spectroscopy.

III. GMR AND MÖSSBAUER RESULTS

Of the four alloys studied, $\text{Cu}_{80}\text{Fe}_{10}\text{Ni}_{10}$ showed the largest values of the magnetoresistance ratio $\text{MR} = [\rho(H) - \rho(H=0)]/\rho(H=0)$. In Fig. 1, we show MR as a function of the applied magnetic field at 4.2 K for $\text{Cu}_{80}\text{Fe}_{10}\text{Ni}_{10}$ ribbons annealed for two hours at the indicated temperatures. Our largest value of $\text{MR} \approx -17\%$ was obtained for an annealing temperature of 400 °C, in agreement with Ref. 7. However, our value of MR is smaller than that reported in Ref. 7, in part, because those authors chose a different normalization for this quantity. For the higher annealing temperatures, the field dependence of MR appears to be nearly linear at high fields.

FIG. 1. Magnetoresistance ratio MR vs magnetic field H for $\text{Cu}_{80}\text{Fe}_{10}\text{Ni}_{10}$ at 4.2 K for different annealing temperatures.

^{a)}Electronic mail: fmissell@macbeth.if.usp.br

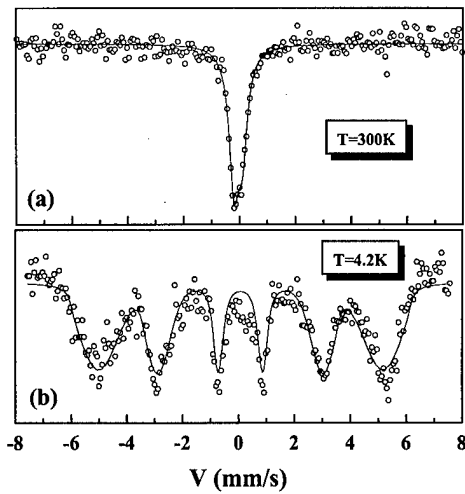

FIG. 2. Mössbauer spectrum for $\text{Cu}_{80}\text{Fe}_{10}\text{Ni}_{10}$ ribbon annealed at 400°C for two hours. Measurements at (a) 300 and (b) 4.2 K.

To characterize the magnetic state of the nanoparticles in these ribbons, all samples were characterized by Mössbauer spectroscopy. At both 78 and 300 K, Mössbauer spectra for all CuFeNi ribbons, both as-cast and annealed, showed a singlet associated with superparamagnetic Fe. The 300 K spectrum for $\text{Cu}_{80}\text{Fe}_{10}\text{Ni}_{10}$ is shown in Fig. 2(a). At 4.2 K, however, the temperature is below the blocking temperature for the Fe nanoparticles and the characteristic Fe sextet appears as shown in Fig. 2(b). The solid curve superimposed on the data of Fig. 2(b) corresponds to a fit made using a Gaussian distribution of hyperfine fields. The Gaussian was centered at 314 kOe and had a width of 82 kOe. For comparison, we note that $\alpha\text{-Fe}$ has a hyperfine field of about 340 kOe at 4.2 K. As we discuss below, magnetization measurements at 300 K on $\text{Cu}_{80}\text{Fe}_{10}\text{Ni}_{10}$ allowed us to estimate $2.1 \mu_B/\text{Fe}$ for this material, characteristic of $\alpha\text{-Fe}$. Thus, both magnetization and Mössbauer measurements indicate the presence of nanoparticles with composition close to that of $\alpha\text{-Fe}$.

The observed hyperfine field reduction can be explained by the collective oscillation model for small particles.⁸ From the expression $H_{\text{part}}/H_{\text{bulk}} = 1 - kT/2KV$, we obtained an estimate for the anisotropy energy barrier $KV/k = 26$ K. This value yields a Mössbauer blocking temperature of order 15 K, which is consistent with our experiments. Assuming $K \approx 4.8 \times 10^4 \text{ J/m}^3$, we obtain a mean radius 1.2 nm for the Fe nanoparticles. This is at least an order of magnitude smaller than the value reported⁹ for Fe nanoparticles in splat-cooled and annealed $\text{Cu}_{75}\text{Fe}_{25}$. To understand this discrepancy, we prepared a sample of $\text{Cu}_{80}\text{Fe}_{20}$ by melt spinning. The Mössbauer spectrum of the as-cast sample at 300 K showed a singlet superimposed upon a well-defined sextet, indicating the presence of many large Fe particles with blocking temperatures above 300 K. Apparently the presence of Ni in the alloy facilitates the formation of a solid solution and results in a greater dispersion of the Fe in the Cu matrix.

IV. GMR VS. MAGNETIZATION

As mentioned in the introduction, a study of the dependence of MR on the reduced magnetization can furnish a

useful characterization of the material as well as important insights into the mechanisms responsible for this effect. This article follows a treatment developed in Ref. 4, which, in first approximation, neglects interactions between particles, but considers a log-normal distribution of magnetic moments associated with the superparamagnetic particles. When the magnetic moment distribution function is used to fit the magnetization curve, one obtains two parameters associated with the distribution curve, which can then be used to calculate the mean magnetic moment and the particle density. Using the same distribution function in a model¹⁰ for the MR provides information on electron scattering within the magnetic grains and at magnetic-nonmagnetic interfaces.

Thus our first task is to determine the normalized curves of magnetization and MR. For this study, we considered $\text{Cu}_{80}\text{Fe}_{10}\text{Ni}_{10}$ because the MR was largest for this sample. However, we considered $T = 300$ K, since the ferromagnetic hysteretic contribution to M was very small at this temperature and it was straightforward to determine the anhysteretic magnetization curve. Since the magnetization had not saturated at 70 kOe, data were fitted to the expression $M = M_s(1 - a/H)$ in order to obtain the saturation magnetization M_s . We obtained $M_s = 19 \text{ emu/g}$ ($2.1 \mu_B/\text{Fe}$), as mentioned above. The MR data were also fitted to a similar expression to determine the saturation magnetoresistance MR_s : $\text{MR} = \text{MR}_s(1 - b/H)$. If $\text{MR} \sim (M/M_s)^2$, then the constant b should equal $2a$. In fact, we obtained $\text{MR}_s = -5.5\%$ and $b = 2a$. The normalized magnetoresistance $\text{MR}_n = \text{MR}/\text{MR}_s$ was plotted as a function of the normalized magnetization M/M_s and the result is nearly a parabola. Deviations from the parabolic form are subtle and must be characterized with care.⁴

The normalized magnetization data up to 70 kOe were then compared with an expression⁴ wherein the magnetization of a distribution of superparamagnetic grains is given in terms of the Langevin function $L(x) = \coth x - 1/x$

$$M(H, T) = \int_0^\infty \mu L\left(\frac{\mu H}{kT}\right) f(\mu) d\mu. \quad (1)$$

The magnetic moment distribution function $f(\mu)$ is a log-normal function divided by μ

$$f(\mu) = \frac{N}{\sqrt{2\pi}\sigma} \frac{1}{\mu} \exp\left[-\frac{\ln^2(\mu/\mu_0)}{2\sigma^2}\right]. \quad (2)$$

This distribution function has a peak near μ_0 and has width σ . In Fig. 3 we show experimental data for $\text{Cu}_{80}\text{Fe}_{10}\text{Ni}_{10}$ annealed at 400°C . The data agree well with the model below 20 kOe and deviate only slightly above that field. We determined the parameters of $f(\mu)$, $\mu_0 = 450 \mu_B$ and $\sigma = 0.93$, and then calculated the mean magnetic moment per grain $\langle\mu\rangle = 693 \mu_B$ and the number of magnetic grains per gram of material: $N = 3 \times 10^{18}/\text{g}$ for our $\text{Cu}_{80}\text{Fe}_{10}\text{Ni}_{10}$ at 300 K. Using the above value of the mean moment $\langle\mu\rangle$ and a value of $2.1 \mu_B/\text{atom}$ for $\alpha\text{-Fe}$, we estimated the mean radius of a magnetic particle to be $r = 1.6$ nm, in good agreement with the radii of magnetic particles encountered in CuCo ⁴ and consistent with our Mössbauer results presented above.

FIG. 3. Magnetization data for $\text{Cu}_{80}\text{Fe}_{10}\text{Ni}_{10}$ ribbon annealed at 400 °C (circles) compared with model which assumes lognormal distribution of noninteracting superparamagnetic particles.

In Ref. 4, the distribution of magnetic moments was used in a model proposed by Zhang and Levy¹⁰ for granular films based upon the formalism for the magnetoresistance in layered structures. Both bulk and interface scattering contribute to the magnetoresistance by means of the factor $\mu + \alpha \mu^{2/3}$, where the parameter α is proportional to the ratio between the interface and bulk scattering cross sections and has been given in Eq. (9) of Ref. 4. We tried fitting our MR data to this model, using the values of μ_0 and σ determined from the magnetization, and treating α as an adjustable parameter. We used

$$\text{MR}(H, T) = -\frac{A}{N^2} \left[\int_0^\infty (\mu + \alpha \mu^{2/3}) L\left(\frac{\mu H}{kT}\right) f(\mu) d\mu \right]^2, \quad (3)$$

where both A and α are coefficients which do not depend upon H and N is the number of grains per unit volume. The result is shown in Fig. 4. There is good agreement for magnetic fields below about 15 kOe, after which the agreement is somewhat worse. Larger values of α do not bring the calculated (dashed) curve into better agreement with the data. In Ref. 4, the MR data in $\text{Cu}_{90}\text{Co}_{10}$ were in good agreement with the model for fields up to 20 kOe. The authors of Ref. 4 have defined two parameters f and g which measure the flatness of the parabolic relation between MR and M/M_s . Calculating these parameters, we find that their values correspond to the limit of the validity of the model. Therefore, it seems that a further discussion of the relationship between MR and M/M_s in $\text{Cu}_{80}\text{Fe}_{10}\text{Ni}_{10}$ will require an extension of the model of Ref. 4.

V. CONCLUSIONS

Both magnetization and Mössbauer measurements indicate the presence of nanoparticles in $\text{Cu}_{80}\text{Fe}_{10}\text{Ni}_{10}$ with com-

FIG. 4. Normalized magnetoresistance for $\text{Cu}_{80}\text{Fe}_{10}\text{Ni}_{10}$ ribbon annealed at 400 °C (circles) compared with curve calculated using Eq. (3) (dashed curve).

position close to that of α -Fe and effective radius slightly larger than 1 nm. This size is considerably smaller than that found for Fe particles in splat-cooled⁹ $\text{Cu}_{75}\text{Fe}_{25}$, but is comparable to values encountered in $\text{Cu}_{90}\text{Co}_{10}$. Thus $\text{Cu}_{80}\text{Fe}_{10}\text{Ni}_{10}$ and $\text{Cu}_{90}\text{Co}_{10}$ seem to be physically comparable and it is interesting to compare MR results in these materials. The magnetization data for $\text{Cu}_{80}\text{Fe}_{10}\text{Ni}_{10}$ at 300 K were found to be in good agreement with curves calculated assuming a distribution of noninteracting superparamagnetic Fe particles. However, the MR data agreed with the proposed model only for low fields.

Microstructure and giant magnetoresistance of Co–Cu granular films fabricated under the extremely clean sputtering process

Masakiyo Tsunoda,^{a)} Kentaro Okuyama, Makoto Ooba, and Migaku Takahashi
Department of Electronic Engineering, Tohoku University, Sendai 980-77, Japan

In order to clarify the influence of the impurities in the sputtering atmosphere on the microstructure and the giant magnetoresistance (GMR) properties of nanogranular thin films, Co–Cu alloy films were prepared on quartz substrates at room temperature under the different purity of the sputtering atmosphere by changing the base pressure, 10^{-11} Torr extremely clean process (XC) and 10^{-7} Torr lower grade process (LG). The correlation between the microstructure and the GMR of films after an annealing procedure is discussed. As results, we found that; (1) A Co-rich phase combined with oxygen was formed at grain boundary in the films as deposited under the LG process; (2) the gradual progress of the grain growth of precipitates with increasing annealing temperature was observed in the XC-processed films, while the coarse grain growth of the matrix phase, resulting in the abrupt change of magnetoresistance occurred in the LG-processed films. We conclude that regulated impurity concentration in the films is an essential parameter to control the precipitation process from the supersaturated solid solution and to realize the desirable microstructure of the nanogranular GMR thin films. © 1998 American Institute of Physics. [S0021-8979(98)26411-5]

I. INTRODUCTION

The origin of giant magnetoresistance (GMR) observed in nanogranular thin films is a spin-dependent scattering of conduction electrons which occurs at the interface between a nonmagnetic matrix and magnetic fine particles of precipitate.^{1,2} In the case of sputter deposited Co–Cu granular films, supersaturated solid solution and fine particles are generally formed as deposited, and the magnetic fine particles grow by postannealing.^{3,4} Since the precipitating process from the supersaturated solid solution is strongly affected by defects and dissolved oxygen in the films, one can expect the drastic change of the microstructure and the GMR properties of nanogranular films with decreasing impurity concentration in the films. In the present study, in order to clarify the influence of the contaminating impurities obtained during the deposition process, we prepared Co–Cu alloy films by changing the purity of the sputtering atmosphere and investigated the correlation between the microstructure and the GMR of them through heat treatment.

II. EXPERIMENTAL PROCEDURE

$\text{Co}_x\text{Cu}_{1-x}$ (x =atom fraction Co) films 300 nm thick were prepared onto fused quartz substrates at room temperature by using a specialized dc magnetron sputtering machine which enables pumping down to 8×10^{-12} Torr. For the process gas, ultraclean Ar gas (UC-Ar), whose moisture level is less than 1 ppb, was used.⁵ In order to make two different residual impurity levels in the sputtering atmosphere, the base pressure of 3×10^{-11} Torr (extremely clean process: XC process) and 3×10^{-7} Torr (lower grade process: LG process) were prepared respectively by changing the pumping time after venting the chamber with air. The flow rate of the UC-Ar gas during sputtering was 100 sccm to make the

pressure 5 mTorr. The impurity levels of the sputtering atmosphere were calculated as 0.01 ppm for the XC process and 1 ppm for the LG process, respectively.⁵ Annealing was performed in vacuum on a same sample subsequently from 150 to 450 °C for 1 h at each temperature. Microstructure of films was examined by x-ray diffraction (XRD) and transmission electron microscope (TEM). Magnetoresistance was measured at room temperature in the film plane by a dc four probe method with maximum applied field of 14 kOe.

III. RESULTS AND DISCUSSION

A. Microstructure

Figure 1 shows TEM images of $x=0.17$ samples as deposited under the XC and the LG processes, respectively. The characteristic grain diameter of the XC-processed film (≈ 30 nm) is larger than that of the LG-processed film (≈ 20 nm). It is noteworthy that a different phase with bright contrast distinguished from grains is observed at triple points of the grain boundary in the LG-processed film. In order to identify the phase with bright contrast, energy dispersion x-ray spectroscopy (EDS) analysis was performed on the LG-

FIG. 2. Characteristic x-ray profiles from the grain boundary phase (A) and the grain (B) of a $\text{Co}_{0.17}\text{Cu}_{0.83}$ alloy film as deposited under the LG process.

processed film. Figure 2 shows the characteristic x-ray profiles obtained when 1-nm-diam electron beam was focused on the grain boundary phase (A) and on the grain (B), respectively. By comparing these profiles, we can say that the phase at triple points in the LG-processed film has higher concentration of Co than the grains. In addition, oxygen, which is not appeared in the grains, is clearly detected in the grain boundary phase. On the other hand, in the XC-processed film, no intergranular phase is observed in Fig. 1(a), indicating the homogeneous distribution of Co in the whole film. It seems reasonable to suppose that the major impurity element, H_2O in the LG-processed atmosphere is the most probable species affecting the change of the microstructure of the as-deposited films. Namely, H_2O unites preferentially with Co adatoms arrived at the substrate and immobilizes them to be nuclei for the condensation of Co adatoms. In the XC process, because of the lack of this nucleation, grains of homogeneous supersaturated solid solution can grow large.

Figure 3 shows the changes of peak intensity and width of major diffraction line from (111) crystal plane in the XRD profile as functions of annealing temperatures, T_a for $x=0.17$ samples. In the case of XC-processed film, the dif-

FIG. 3. Changes of XRD profiles of $\text{Co}_{0.17}\text{Cu}_{0.83}$ films of the XC process and the LG process, as deposited and after annealed at various temperatures, T_a . Peak intensity (open figures) and width (filled figures) for (111) diffraction line are plotted.

FIG. 4. TEM images of $\text{Co}_{0.17}\text{Cu}_{0.83}$ alloy films of the XC process and the LG process, after annealed at $T_a=200$ and 350°C , respectively.

fracted lines gradually become large and sharp up to 300°C , and turn to become broad above 350°C . On the other hand, in the case of LG-processed film, abrupt increase of intensity and sharpening of diffraction line are observed at 200°C , which suggests a coarse grain growth. Figure 4 shows TEM images of $x=0.17$ films in the both processes after annealed at 200 and 350°C , respectively. In the XC-processed film, corresponding with the changes of XRD profile, the gradual grain growth with increasing T_a is observed. Also we can see the obscure lattice image of grains with increasing T_a , which is suggesting the decomposition of supersaturated solid solution. In contrast, in the LG-processed film, we can see the coarse grain growth at 200°C . The characteristic grain size was larger than several hundred nm. The Co-rich phase which existed at the grain boundary as seen in the as-deposited film with bright contrast [Fig. 1(b)] is cut apart and dispersed in the coarsened matrix grains as fine particles.

B. GMR and magnetic properties

Figure 5 shows the changes of ρ_s and $\Delta\rho (= \rho_0 - \rho_s)$ as a function of the annealing temperature, T_a , for the films with $x=0.13$, 0.17 , and 0.25 fabricated under the XC and the LG processes. ρ_0 and ρ_s are defined as the resistivity measured without and with applied field of 14 kOe, respectively. ρ_s gives a scale of the resistivity when the magnetization of the film is saturated, though 14 kOe was not large enough especially in the films as-deposited and after annealed at lower temperature. We attend to the $x=0.17$ as a typical example. In the XC-processed film, ρ_s which was $52 \mu\Omega \text{ cm}$ as-deposited gradually decreases, with increasing T_a . $\Delta\rho$ which was $1.8 \mu\Omega \text{ cm}$ as-deposited gradually increases and reaches maximum value of $2 \mu\Omega \text{ cm}$ at $T_a=150^\circ\text{C}$, then decreases with increasing T_a . The increase of $\Delta\rho$ below 150°C can be explained by the increasing volume and heightening the Co concentration of the Co-rich phase by precipitation from the supersaturated solid solution. Namely, the enlarging magnetization of Co-rich phase makes film easy to saturate even at 14 kOe and enhances the difference of spin-dependent scattering between zero and maximum applied field. Above 200°C , the decrease of $\Delta\rho$ is explained by

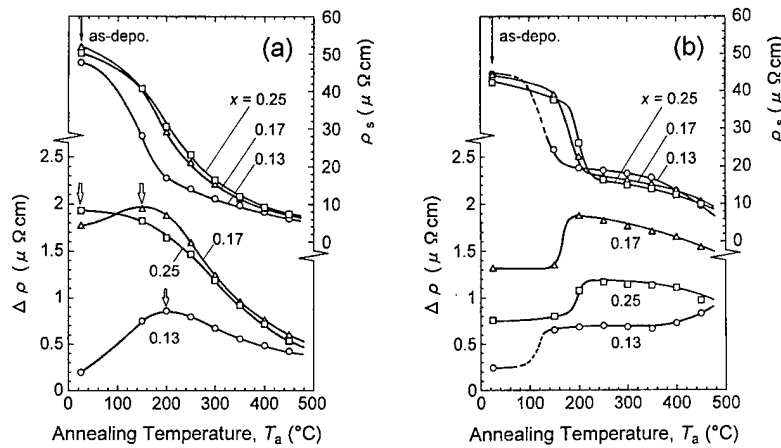

FIG. 5. Changes of resistivity ρ_s and magnetoresistance $\Delta\rho$ as functions of annealing temperature for $\text{Co}_x\text{Cu}_{1-x}$ films of the XC process (a) and the LG process (b).

grain growth of Co-rich phase leading to lower their surface/volume ratio. Here, we should notice the annealing temperature where $\Delta\rho$ reaches maximum (indicated as open arrows in the figure) becomes lower with increasing Co content. This means that highly supersaturated Co are easy to precipitate and to make large grains of Co-rich phase at relatively lower temperature. These experimental facts support the grain growth discussed above. On the other hand, in the LG-processed films, abrupt drop of ρ_s is observed at $T_a = 200^\circ\text{C}$ in $x = 0.17$ case. Corresponding to this change, $\Delta\rho$ steeply increases from 1.3 to 1.9 $\mu\Omega\text{cm}$ at $T_a = 200^\circ\text{C}$. By taking into account the structural change as previously shown in Figs. 3 and 4, one can say that the physical origin of the abrupt changes of ρ_s and $\Delta\rho$ at $T_a = 200^\circ\text{C}$ is the decrease of grain boundary scattering and the randomizing direction of the magnetization of particulate Co-rich phase at zero field. In addition, from the slight decrease of $\Delta\rho$ above 200°C , we can conclude that the grain growth of Co-rich phase resulting from the decomposition of the supersaturated solid solution is not significant in the LG-processed film up to 450°C , contrary to the XC-processed one.

Figure 6 shows the changes of $M_{10\text{ kOe}}$, which is the magnetization measured under applied field of 10 kOe, and

the coercivity, H_c of $x = 0.17$ samples as a function of T_a . Measurement was performed at room temperature. In the XC-processed film, $M_{10\text{ kOe}}$ gradually increases with increasing T_a . H_c arises from $T_a = 200^\circ\text{C}$ and also increases gradually, indicating that magnetic stability against thermal agitation is induced by grain growth of the Co-rich phase. On the other hand, in the LG-processed film, $M_{10\text{ kOe}}$, which is 190 emu/cc as-deposited and larger than that of the film in the XC process, slowly increases and becomes smaller than the XC process above 350°C . H_c also increases fairly slightly up to 450°C . These changes well correspond with the changes of microstructure and the GMR discussed above.

IV. CONCLUSION

Co-Cu alloy films were fabricated under the different purity of the sputtering atmosphere by changing the base pressure, 10^{-11} Torr (XC process) and 10^{-7} Torr (LG process). The correlation between the microstructure and the giant magnetoresistance of Co-Cu alloy films was examined. As results, we found that: (1) A Co-rich phase combined with oxygen was formed at grain boundary in the as-deposited films in the LG process; (2) the gradual progress of the grain growth of Co-rich phase with increasing annealing temperature, accompanying a gradual change of magnetoresistance, were observed in the XC-processed films; (3) in the LG-processed films, the coarse grain growth of the matrix phase resulted in abrupt change of magnetoresistance.

We conclude that the regulated impurity concentration in the films is an essential parameter to control the precipitation process from supersaturated solid solution and to realize the desirable microstructure of the nanogranular GMR thin films.

E. F. Ferrari

Instituto de Física "Gleb Wataghin", UNICAMP, C.P. 6165, 13083-970, Campinas, SP, Brazil

We present experimental magnetoresistance, magnetization, and remanence data for CoCu granular films obtained by electron beam codeposition, subsequently submitted to a thermal treatment. The magnetization measurements show coexistence of superparamagnetic and ferromagnetic (or blocked superparamagnetic) Co grains. By modeling the experimental magnetization curves, the distribution function of the superparamagnetic particle size, the volume fraction of the blocked part of the Co particles, and their saturation magnetization are obtained. δM plots are constructed using the remanence curves. A correlation between the changes of the δM parameters and those of the giant magnetoresistance, caused by the annealing, is discussed. © 1998 American Institute of Physics. [S0021-8979(98)46811-7]

I. INTRODUCTION

The so-called granular ferromagnetics are composites of two materials, one of which consists of nanosized ferromagnetic particles (e.g., Fe, Co) dispersed in nonmagnetic metallic matrix (e.g., Ag, Cu, Au). Since the discovery of the effect of giant magnetoresistance (GMR) in such systems,^{1,2} they have been widely investigated due to their potential for practical applications and because they can be easily produced (usually sputtering, coevaporation, melt spinning, mechanical alloying, or electrodeposition), and their microstructure can be modified by suitable thermal treatment. The GMR in these granular systems is comparable to the ones found in multilayers. Extensive studies have been made to link the GMR response to the structural properties (e.g., interface, particle shape, size and density, intergranular distances, etc.).^{3,4}

The GMR effect in these systems is believed to be a manifestation of the conduction electron spin-dependent scattering on the local magnetic configuration. Qualitatively, it is assumed that the scattering probability is proportional to the correlation degree of the moments of adjacent pair of granules $\langle \mu_i \cdot \mu_j \rangle$.^{5,6} The resistance of the heterogeneous alloys is maximum in the case of random distribution, i.e., low correlation of magnetic moments at zero field. The applied field aligns the magnetic moments (high correlation) thus decreasing the resistance of the system.³

The magnetoresistive behavior of an homogeneous superparamagnetic (SPM) system has a relatively simple interpretation based on a description by the Langevin function. In this case it is given by $[L(\mu H/k_B T)]^2$, where H is the applied field, k_B the Boltzman's constant, and T the temperature. All the theories that use this description predict a dependence of the fractional magnetoresistance on the square of the reduced magnetization. However, this relation fails in some granular systems.⁷ Interparticle interactions⁸ and de-

pendence of the scattering process on cluster size⁹⁻¹¹ are the mechanisms that have been introduced to explain this discrepancy.

The effect of interactions on GMR of granular solids has been investigated,¹² using a model that obtain the moment configuration in the presence of dipolar magnetic fields. The GMR effect is found to be lowered by these interactions, and connected to low-range correlation of the magnetic moments. In this case, a deviation from the parabolic law is also observed. In the present work, the influence of the thermal treatment on the microstructure, magnetoresistance, and magnetic properties of CoCu codeposited films is investigated. The latter, along with the fact that the GMR for our samples do not saturate for the maximum magnetic field available, do not allowed us to use the deviations from the parabolic law to estimate the interaction effects. We used the technique based on the δM^{dc} plot, which has been extensively used recently, because it proved to be very sensitive to small changes in the remanence produced by interaction between the magnetic regions of the system.

II. EXPERIMENT

The 5000-Å-thick Co-Cu films with different compositions were codeposited by means of electron beam gun on Si (111) substrate. The nominal compositions are 10%, 20%, and 30% of cobalt. Thermal treatment was performed in a rapid annealing furnace under Ar atmosphere between 100 and 350 °C for 1 h. The magnetization and remanence curves were measured at room temperature using an alternating gradient magnetometer with the field applied parallel to the sample's plane. The magnetoresistance curves were measured in fields up to 6 kOe using the standard four points method.

III. RESULTS AND DISCUSSION

The conventional x-ray diffraction shows a pure fcc Cu structure, no traces of hcp Co are observed. Due to the small

^{a)}Electronic mail: dcviegas@if.ufrgs.br

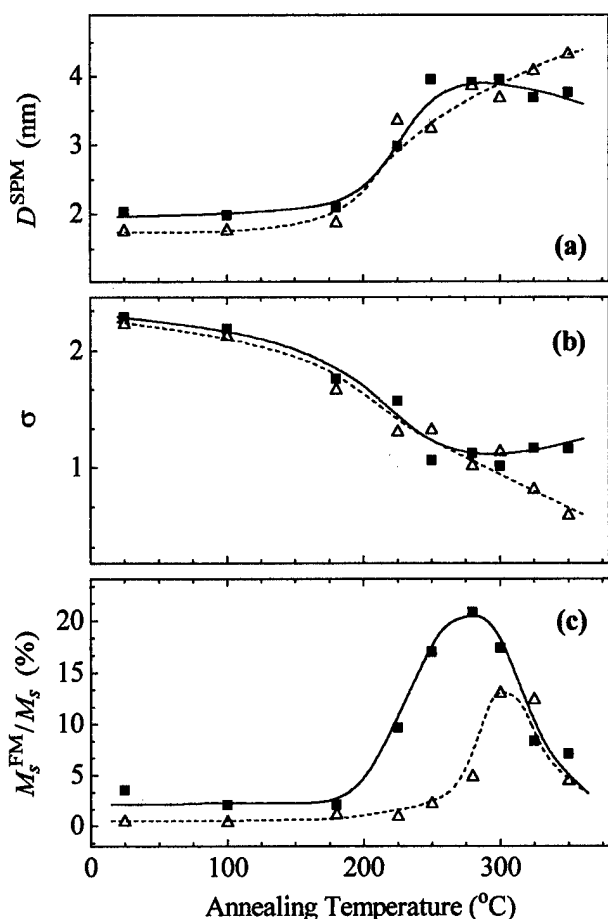

FIG. 1. (a) D^{SPM} and (b) σ vs. T_{ann} obtained from the SPM fit of the experimental magnetization curves for the samples with 10% and 20% Co concentrations; (c) The ratio between FM component and total magnetization; squares: 10% Co, and triangles: 20% Co. The lines are guide to the eye.

size of the Co particles and the high lattice coherency between the fcc Co phase and the Cu matrix, this Co phase cannot be distinguished.

The experimental magnetization curves show hysteresis. Here, as in our previous work,¹³ we consider the samples as consisting of two magnetic Co phases: (i) noninteracting SPM particles and (ii) “blocked” [interacting and/or larger ferromagnetics (FM)] grains. The sample magnetization can be written as $M(H) = M^{\text{FM}}(H) + M^{\text{SPM}}(H)$. The M^{SPM} term is a weighted superposition of Langevin functions assuming the following magnetic moment distribution function¹⁴

$$f(\mu) = \frac{N}{\sqrt{2\pi}} \frac{1}{\mu} \exp\left[-\frac{\ln^2(\mu/\mu_0)}{2\sigma^2}\right], \quad (1)$$

where N is the volumetric SPM particle density, μ_0 the particle magnetic moment, and σ the width of the distribution which differs from the log-normal one by the factor $1/\mu$. The mean value of μ is defined as $\langle\mu\rangle = \mu_0 \exp(\sigma^2/2)$.

In Figs. 1(a) and 1(b) the values of the mean SPM particle size, D^{SPM} , and σ used to fit the SPM components of the experimental magnetization curves are displayed as a function of the annealing temperatures, T_{ann} for the samples with 10% and 20% Co concentrations. Due to the low SPM

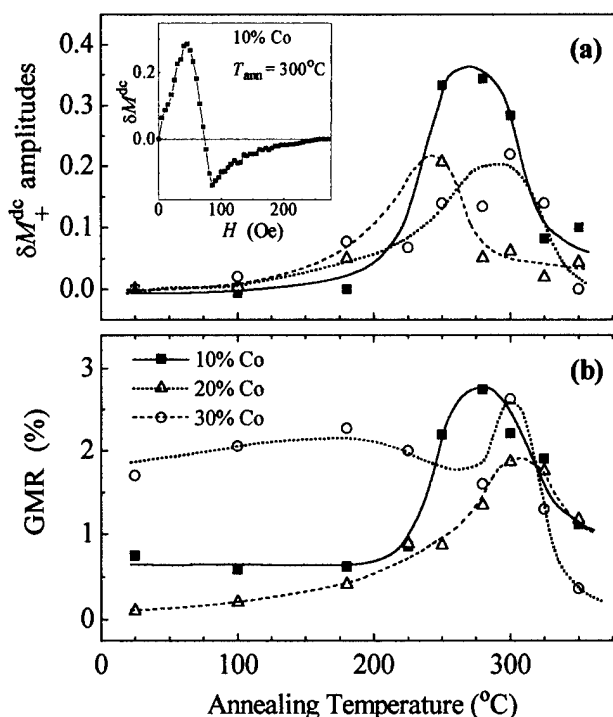

FIG. 2. (a) δM^{dc}_+ vs. T_{ann} constructed from the remanent magnetization curves; the inset in this figure is a representative δM^{dc} plot for the sample with 10% Co, annealed at 300 °C. (b) GMR vs. T_{ann} for samples with different Co concentration. The lines are guide to the eye.

contribution to the total magnetization of the 30% Co sample, it was not possible to fit its SPM component. The dependence of the FM fraction, defined as M_s^{FM}/M_s , on T_{ann} is shown in Fig. 1(c) (the method of estimation of M_s^{FM} is described elsewhere).¹³

When the particles are sufficiently close to each other, the magnetic interactions can induce correlation between the adjacent moments, which may be both Ruderman–Kittel–Kasuya–Yosida (RKKY) and/or dipolar in nature. We tried to estimate this effect by using the maxima of the δM^{dc} plots, defined in our recent works.^{13,15} The positive amplitude values, δM^{dc}_+ vs T_{ann} are represented in Fig. 2(a) (the negative ones almost do not change as a function of T_{ann} having values of ≈ 0.2). The inset in Fig. 2(a) shows a representative δM^{dc} plot (10% Co, $T_{\text{ann}} = 300$ °C). The reduced GMR values, defined as $[R(H) - R(H=0)]/R(H=0)$, obtained for $H_{\text{max}} = 6$ kOe, are shown in Fig. 2(b).

$T_{\text{ann}} \leq 200$ °C does not change significantly the morphology, magnetic, and magnetotransport properties of the samples. Figure 1(c) shows that in this T_{ann} range, the samples contain mostly SPM particles, with $D^{\text{SPM}} \approx 2$ nm. M_s values are rather smaller than M_s^{Co} for bulk Co, indicating that there is a large number of Co atoms dissolved in the Cu matrix.

Annealing at higher temperatures up to approximately 300 °C, results in a gradual increase of D^{SPM} and a decrease of σ , i.e., the SPM particles become larger and more uniform in size. Their number increases as well, as the total M_s values increase for all samples at the expense of the atomically diluted Co in the Cu matrix. GMR is enhanced, reaching its maximum for $T_{\text{ann}} \approx 300$ °C for all samples (for H_{max}

=6 kOe). This increase could be explained, assuming that the main contribution to the GMR comes from the random orientation of the SPM Co magnetic moments:² annealing at higher temperatures increases the number of SPM particles, changes their size, and the mean distance between them. The latter would become comparable to the mean free path of the conduction electrons, and more selective scattering would occur, thus increasing GMR. Although the FM fraction increases with increasing T_{ann} , it remains relatively small and does not influence the GMR, as observed from the magnetoresistance curves, which do not show rapid response at low fields and do not saturate at 6 kOe.

GMR of the samples annealed at $T_{\text{ann}} > 300^\circ\text{C}$ decreases, despite that the D^{SPM} and σ do not change significantly. However, a decrease of the total M_s is observed for all samples, which can be explained by the decrease of the number of the SPM particles, as well as the increase of the distance between them, so the scattering event becomes infrequent and far apart, thus GMR is small. The decrease of M_s is not very clear, but we suggest that some Co is redissolved in the Cu matrix,¹⁶ which is expected to be present at high temperature.

All δM^{dc} plots are characterized by positive peaks in low fields and a relatively shallow minima in higher fields. There are two cases to be considered.

(i) the FM particles are mainly fcc Co, and weak positive (ferromagnetic, magnetizing) interactions present. This suggestion is supported by the similarity of the shape of the experimental δM^{dc} plots to that calculated for a disordered system of noninteracting cubic anisotropy particles with four easy magnetization axes,¹³ as well as by the statement of Kimoto *et al.*¹⁷ and Anno,¹⁸ that small Co particles have a fcc structure. In this case, the increase of δM^{dc} by increasing T_{ann} means that the interactions favoring parallel alignment weaken, and δM^{dc} tends to reach the value of ≈ 0.5 of that calculated for the noninteracting case plot.¹³ Thus, the maximum of the GMR, which is in the same T_{ann} range where δM^{dc} is maximum, can be associated with the weaker interactions, even that the FM fraction is not very large, having its maximum of $\approx 20\%$ for 10% and 20% Co.

(ii) The samples consist of hcp (uniaxial) Co. In such cases, positive deviations from the noninteracting zero line¹⁹ are attributed to strong FM interactions between the adjacent grains. The increase of δM^{dc} by increasing T_{ann} suggests increase of these interactions, and as result, GMR should be depressed, on the contrary of what is observed here. Therefore, we believe that the data support the first suggestion—the Co is mainly in fcc phase.

The reduction of δM^{dc} for the higher T_{ann} can be attributed not to an increase of the negative interactions, but mainly to an extinction of the FM phase, as indicated in Fig. 1(c).

IV. CONCLUSION

Experimental magnetoresistance and magnetization data for thermally treated CoCu codeposited films were reported. It was obtained that the GMR has maximum of $\approx 3\%$ (for $H_{\text{max}} = 6$ kOe) when the SPM particles have a specific size range and their size distribution width is relatively narrow. Assuming that the Co particles are mainly fcc, a correlation between the changes of the δM parameters and of GMR is observed. However, as the relative FM fraction is rather low in our samples, one should not assume that the magnetic interactions are the main, determining factor for the GMR changes.

Structural and magnetic properties of "expanded" Mn deposited on (111) oriented fcc noble metals were studied with single-crystal x-ray diffraction and exchange bias measurements. A single peak corresponding to this phase was found at momentum transfer $q=2.86 \text{ \AA}^{-1}$ along six equivalent [112] directions of the noble metal substrate. Magnetic hysteresis of the field cooled Fe/Mn bilayers exhibited a characteristic shift along the field axis, indicating antiferromagnetic order in the expanded Mn with $T_N \geq 20 \text{ K}$. The magnetic and structural data are consistent with understanding the expanded phase as trigonally distorted α -Mn. © 1998 American Institute of Physics. [S0021-8979(98)37511-8]

I. INTRODUCTION

The properties of Mn epitaxially grown on close-packed surfaces has recently generated much interest. Deposited on these surfaces, Mn first assumes a close-packed structure with a lattice parameter close to that of fcc Mn. When the layer exceeds a critical thickness, which ranges between 2 and 12 Å, depending on the substrate material, Mn undergoes a $\sqrt{3} \times \sqrt{3}$ reconstruction. This new structure is called the "expanded" phase.¹⁻⁴ Based on the well-known ability of Mn to form crystals with ions of different sizes, Arrott *et al.*¹ developed a model in which expanded Mn was treated as a Lave phase of Mn with itself. Specifically, hexagonal-close-packed (hcp) MgZn₂ and fcc MgCu₂ alloys were proposed as possible prototypes for the expanded phase. Three-dimensional reflection high energy electron diffraction (RHEED) analysis of Mn grown on hcp Co (0001) suggested that the structure of expanded Mn was closest to (111) oriented MgCu₂.³ This is in contradiction to the results of recent extended x-ray absorption fine structure (EXAFS) measurements of Mn grown on Ir(111).⁵ In fact, the best fit to the experimental EXAFS spectra was achieved when expanded Mn was treated as a 50%–50% mixture of γ -Mn (fcc) and ground state α -Mn. Attempts to determine the magnetic properties of expanded Mn resulted in a similar controversy. The results of all studies agreed on the antiferromagnetic nature of this phase, but ordering temperatures ranging from 30 to above 320 K were reported.^{4,6}

Determination of the structure of expanded Mn is complicated by the fact that this phase does not have clearly identifiable x-ray Bragg peaks with the momentum transfer

in the growth direction. In addition, the magnetic susceptibility of expanded Mn is small,⁴ so the minor changes in magnetic background obscure the results of susceptibility measurements. In this study, experimental techniques have been chosen to bypass these complications. Grazing incidence x-ray diffraction (GID)⁷ has been used to analyze the scattering from expanded Mn in the plane of the film. The magnetic properties of Mn have been tested in an exchange-bias experiment (similar to the one used in Ref. 6), which is capable of distinguishing between paramagnetic and antiferromagnetic order in a material via its interaction with an adjacent ferromagnetic layer.

II. SAMPLE PREPARATION

Expanded Mn was grown on Cu(111) and Ag(111) base layers predeposited on epi-polished MgO(111) single-crystal substrates covered with a 15 Å thick seed layer of Mn. The temperature of the substrate was maintained at 200 °C during the growth of the seed and base layers. After deposition of the base, the substrate was cooled to 0 °C and further growth proceeded at temperatures between 0 and 25 °C. The surface crystallinity was monitored via *in situ* RHEED. The samples used for structural analysis [Fig. 1(b) inset] consisted of a single layer of Mn on the base. The samples for magnetic characterization [Fig. 2(b) inset] contained a layer of Fe on top of the Mn.

The difference between Cu and Ag cubic lattice parameters is 13%, which yields diffraction peaks well separated in reciprocal space. The choice of these materials for Mn growth insured that weak reflection(s) from Mn would not be overshadowed by diffraction from the base in at least one of the samples. The epitaxy of Mn on either of these substrates has not yet been studied. The lattice parameter of the close-packed (111) Cu surface is within the range of the lattice

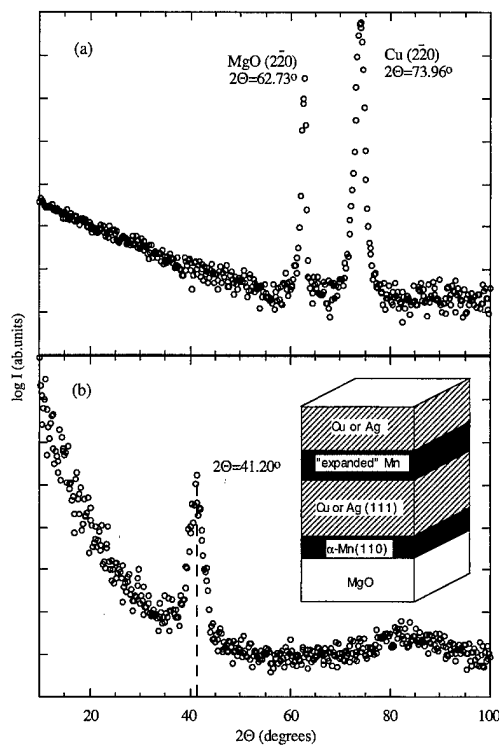

FIG. 1. GID Θ — 2Θ scan for Cu-based sample. (a) $q||$ MgO $[1\bar{1}0]$. (b) $q||$ MgO $[112]$. Inset: sample for the GID experiment.

parameters of the surfaces on which the growth of the expanded Mn has been observed; the lattice parameter of Ag is well outside this range. Indeed, the growth of Mn proceeded differently on each base. On Cu, formation of the expanded phase followed the growth of 2–3 Å of close-packed Mn, while on Ag, the intermediate close-packed phase did not form at all and Mn grew in the expanded phase from the onset. With increasing thickness, the RHEED streaks broadened and diffuse background increased, suggesting increasing roughness of the Mn surface. This deterioration was greater in films grown on Ag(111).

III. STRUCTURAL CHARACTERIZATION

Diffraction spectra for the sample containing an 80 Å Mn layer on Cu(111) are shown in Fig. 1. Along the $[1\bar{1}0]$ direction (upper plot) two peaks correspond to MgO (220) and Cu (220) Bragg reflections. These are the only in-plane reflections expected from (111) oriented fcc Cu and MgO for the x-ray wavelength $\lambda = 1.54$ Å. Diffraction with q along the $[112]$ direction (lower plot) produced a single peak at $2\Theta = 41.20^\circ$ ($|q| = 2.86$ Å $^{-1}$). This peak was found to be sixfold symmetric with respect to sample rotation around the film normal. Identical measurements performed on the sample containing a 55 Å thick Mn layer on Ag(111) produced similar spectra, with the Ag(220) peak replacing the Cu peak in Fig. 1. The in-plane diffraction spectra of a reference sample (Cu base on MgO(111)) showed no peaks in the $[112]$ direction. This result and the sixfold symmetry of the $q_{112} = 2.86$ Å $^{-1}$ peak imply that it arises from expanded Mn.

Two finer points are also worth mentioning in this re-

gard: (a) an extremely weak peak at $q_{111} = 2.94$ Å $^{-1}$ was observed in out-of-plane diffraction spectra of the samples grown on Ag, but not on Cu (an identical peak was also reported in Ref. 5); (b) the x-ray momentum transfer in $[112]$ direction does not match the surface reciprocal lattice vector in the same direction (2.69 Å $^{-1}$) obtained by *in situ* RHEED.

Diffraction peaks obtained from expanded Mn are inconsistent with either fcc or Lave phase structures. The discrepancy between the surface and bulk momentum transfer indicates a difference between bulk and surface periodicities. This suggests a rather complicated atomic arrangement in expanded Mn. We observed a similar discrepancy in α -Mn(110) grown at elevated temperature on MgO(111). A qualitative analysis of the atomic arrangement in α -Mn(110) suggests that the symmetry and size of the surface unit cell observed in the expanded phase may be achieved from α -Mn by a combination of a strain along the $[110]$ direction and a shear along the $[001]$ direction. Such a distortion would reduce the symmetry of the crystal to trigonal. To explain the x-ray data one has to invoke an additional lattice expansion in the plane of the film.

IV. MAGNETIC CHARACTERIZATION

The magnetic properties of expanded Mn were investigated by coating it with a 10–30 Å thick Fe film and measuring the exchange bias induced across the Fe/Mn interface. Initial growth of Fe on Mn was characterized by a gradual decrease in the intensity of Mn RHEED streaks. Upon deposition of approximately 12 Å of Fe, a sharp RHEED pattern, corresponding to multidomain bcc Fe (110), was observed. Nevertheless, in samples containing more than 10 Å of Mn on Ag(111) and more than 20 Å of Mn on Cu(111), weak and fuzzy RHEED reflections from Mn were observed along with the Fe diffraction pattern even for an Fe thickness of 30 Å. The absence of the Fe RHEED pattern for low coverages and the coexistence of the RHEED patterns at higher coverages indicate significant short-scale roughness of the Fe/Mn interface. Mössbauer spectroscopy of the Fe layer suggests that the microscopic interdiffusion of Fe and Mn was confined to the first 1–2 ML (at least in the smoothest samples) while the remainder of the Fe layer showed properties close to that of bulk bcc Fe.

Exchange bias in Fe/Mn bilayers was measured by field cooling the sample in 5 kG applied in the plane of the film and recording the hysteresis curve of the ferromagnetic layer. The measurements were performed in a superconducting quantum interference device (SQUID) magnetometer with a typical offset field of ≈ 4 Oe. The magnitude of the exchange field H_E (shift of the center of the hysteresis from $H = 0$) was studied as a function of temperature. In a system where an antiferromagnet and a ferromagnet have a common interface, H_E is nonzero below the blocking temperature T_B , somewhat lower than the Néel temperature of the antiferromagnet.⁸ The value of T_B may thus be used to place a lower limit on T_N .

The temperature dependencies of the exchange field in Fe/Mn bilayers grown on Ag and Cu bases are shown in Fig. 2. In all samples, a nonzero exchange bias at temperatures

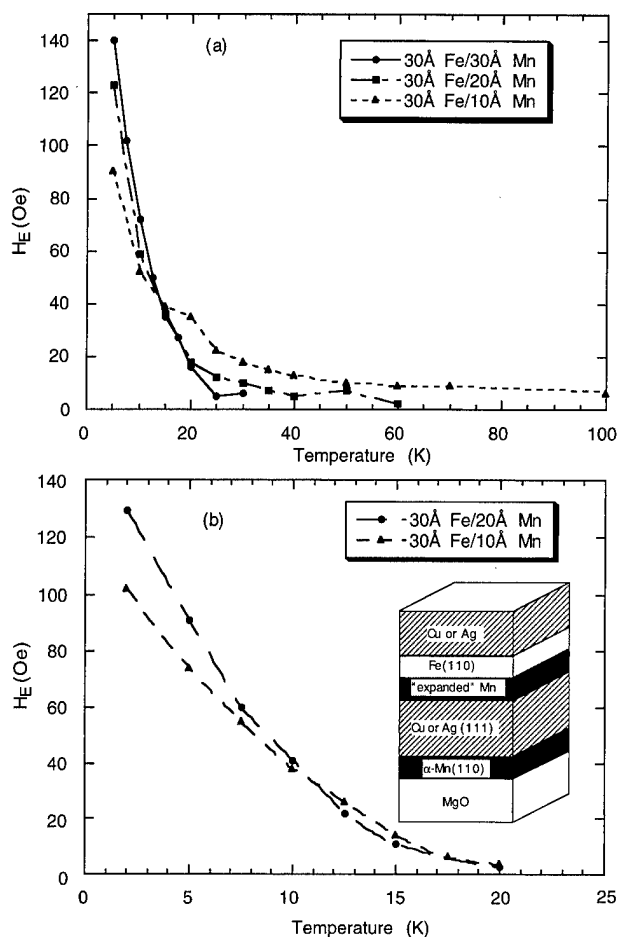

FIG. 2. Exchange field as a function of temperature in the bilayers grown on (a) Cu(111) and (b) Ag(111). Inset: sample for magnetic characterization.

below 20 K indicated antiferromagnetic order in expanded Mn. The temperature dependence of the bias in the films with different Mn thickness was noticeably different, depending on the base. In samples grown on Ag, the blocking temperature showed no dependence on Mn thickness. On Cu, decreasing the thickness of the Mn layer resulted in the region of nonzero $H_E(T)$ extending to higher temperatures [Fig. 2(a)].

V. DISCUSSION

The exchange bias effect originates from the spin interactions across the ferromagnet–antiferromagnet interface and therefore may be affected by the roughness of the interface. In Fe/Mn bilayers, the roughness is due to the roughness of the bare Mn layer which increased with increasing thickness, most rapidly when grown on Ag. Since all Ag based samples exhibited the same $T_B \approx 20$ K, independent of Mn thickness, roughness can be eliminated as a reason for the drop in T_B with increasing Mn thickness in samples grown on Cu.

Alternatively, the observed behavior of T_B in samples of different composition may be explained if the fraction of γ -Mn grains in the layer is taken into account. The γ -Mn is antiferromagnetic with a Néel temperature of 540 K, so the presence of this phase should alter the magnetic properties of the Mn layer and specifically the blocking temperature mea-

sured in the exchange-bias experiment. The presence of γ -Mn grains in Mn layers grown on hexagonal surfaces has been suggested before, in reference to Mn/Co³ and Mn/Ir⁵ multilayers, although the spatial distribution of this phase across the layer remains unknown.

It is reasonable to assume that different substrates promote γ -Mn growth to a different degree. The major indication of this dependency comes from the different Mn layer thicknesses at which $\sqrt{3} \times \sqrt{3}$ reconstruction of the RHEED pattern occurs in different systems. Among the samples analyzed in this study, the epitaxial growth of γ -Mn occurred in Cu-based samples (lattice mismatch 3%) and not in Ag-based samples (lattice mismatch –9%). The RHEED observations discussed in Sec. II suggest that even in the most favorable case (Cu base), the γ -Mn is confined to a few monolayers closest to the substrate.

Because of this confinement, increasing the Mn thickness on Cu-based samples leads to a decreasing fraction of γ -Mn in the layer. Our data correlates this decrease with the drop in T_B . On Ag, the Mn layer consists of the pure expanded phase and samples with different layer thickness show the same $T_B \approx 20$ K. Roughly the same value of T_B is observed in the sample containing the thickest Mn layer grown on Cu (30 Å). This interpretation also helps explain the high value of $T_B \approx 320$ K observed in Co/Mn multilayers where the presence of fcc grains was more apparent.³

Finally, the small value of T_B in the expanded Mn is also consistent with this phase being a distorted α -Mn ($T_N = 95$ K). If the $(3\bar{3}0)$ reflection of α -Mn is taken as a reference point ($|q| = 2.99 \text{ \AA}^{-1}$), expanded Mn results from 5% expansion within the (110) plane. Based on the out-of-plane peak observed in Ag-based samples, 2% expansion in that direction may be argued. An increase in atomic volume can result in the decrease of the absolute value of the exchange between magnetic ions which would lead to a suppression in T_N .

In conclusion, the structural data obtained in this study suggest that the atomic arrangement in the expanded phase of Mn is similar to that of trigonally distorted α -Mn. Pure expanded Mn is antiferromagnetic with a Néel temperature likely equal to or below that of α -Mn, which is also consistent with the proposed distortion. Higher values of T_B , also seen in previous studies, may be attributed to the presence of fcc grains.

Structural properties of Mn films, with a thickness of one monolayer (ML), deposited on a Ag(100) substrate have been investigated both experimentally (photoemission and ion scattering spectroscopies) and theoretically (tight-binding linear muffin-tin orbital method). The magnetic structure of the films and the effect of magnetism on their relative stability have been investigated *ab initio*. We find that after Mn evaporation [at room temperature (RT)], a superficial MnAg alloy is formed. Mild annealing gives rise to the formation of an (almost) inverted Mn monolayer covered by a Ag plane, i.e., the second atomic plane of the sample is mainly constituted by Mn atoms, whereas the first atomic layer is almost a pure Ag plane. A complete inversion of the Mn ML can be obtained by direct sequential deposition of Mn and Ag at 80 K. Our calculations on the energetic stability of 1 ML of Mn on top of Ag(100) versus 1 ML of Mn covered by one Ag atomic plane, show that the second situation is energetically preferred. This is also true when this situation is compared to the formation of a 2-ML-thick MnAg alloy on Ag(100). We find that the inverted Mn monolayer tends to be ferromagnetic and that magnetism acts against interdiffusion. © 1998 American Institute of Physics. [S0021-8979(98)29111-0]

Much work has been devoted in the last years to the growth and magnetic properties of thin transition metal films deposited on noble metals.^{1,2} Interesting magnetic effects are expected when a species grows on a substrate with a crystallographic structure that is different from its bulk one. In this respect, we have grown Mn ultrathin films on a Ag(100) substrate and analyzed the resulting overlayers by ion scattering spectroscopy (ISS) and x-ray photoelectron diffraction (XPD). We show that deposition of 1 monolayer (ML) of Mn on Ag(100) at room temperature (RT) gives rise to a pseudomorphic superficial alloy where the Mn atoms are confined within the first and the second (but not in deeper) atomic layers. Annealing the film or depositing the Mn at a higher temperature (however <350 K) causes the Mn atoms, initially in the first layer, to occupy sites in the second layer. To complete this structural study we have performed *ab initio* electronic band structure calculations. The experimental and theoretical results are in good agreement and show evidence of an inverted Mn ML, i.e., 1 ML of Mn covered by one Ag plane. Experimentally, this inverted monolayer is found to be stable up to ≈ 350 K, with Ag atoms substituted by Mn atoms in deeper layers above this temperature.

The experiments were conducted in an ultrahigh vacuum chamber equipped with photoemission, low energy electron diffraction (LEED), and ISS techniques. The Mn was deposited at a low rate, typically 0.2 ML/min, onto Ag(100) substrate which had been prepared *ex situ* by mechanical and chemical polishing and cleaned *in situ* by sputtering and annealing. The Mn coverage was determined by a quartz microbalance as well as core level photoemission. The base

pressure was below 4×10^{-10} Torr, even during evaporation, and contamination levels were below the detection limit. Figure 1 shows typical Mn $2p_{3/2}$ XPD profiles, obtained in the [001] high symmetry plane of the Ag substrate, for 0.9 ML of Mn deposited at 80 K and 300 K. As can be seen, the relevant data do not show any modulations when growth takes place at 80 K, i.e., the Mn must lie flat on top of the Ag substrate. If bilayer formation or alloying were to take place, one should observe strong forward scattering of the photoelectrons emitted by Mn in the second or deeper atomic layers. Such a strong forward scattering peak becomes apparent indeed in the [001] plane at a polar angle $\theta=45^\circ$ when the Mn is deposited at RT. In the [110] plane, however, the profiles (not shown) remain quite isotropic for all structures considered here. This can be simply interpreted in terms of formation of a surface alloy involving the two topmost atomic layers, which are mixed MnAg layers.³⁻⁵ This surface alloy keeps the Ag face-centered-cubic (fcc) lattice, with the same parallel and perpendicular parameters, and exhibits a composition close to $\text{Mn}_{0.5}\text{Ag}_{0.5}$, as well as a $c(2 \times 2)$ superstructure immediately after deposition. Moreover, it appears to be unstable upon annealing at RT³ or above. The effect of mild annealing at 330 K is summarized in Table I. On one hand, the composition of the topmost layer as determined by ISS evolves from $\approx 40\%$ of Mn for a sample left about 100 min after deposition at RT, to 27% of Mn after annealing at 330 K. On the other hand, Mn enrichment of the second atomic layer shows up in a marked increase of the 45° forward scattering peak: The anisotropy $A = [I(45^\circ) - I(30^\circ)] / [I(45^\circ) + I(30^\circ)]$ increases from 20% to 24%. This is because only Mn atoms in the second layer contribute to the forward scattering peak. Actually, a

FIG. 1. Angular distributions of the Mn $2p_{3/2}$ core level intensity in the [001] plane for 0.9 ML of Mn after deposition at 80 K (bottom) and at RT (middle), and for 0.9 ML of Mn+0.9 ML of Ag deposited at 80 K and annealed at RT (top). The photon energy is 1486.6 eV Al K_{α} and the kinetic energy of the Mn $2p_{3/2}$ photoelectrons is about 849 eV. The polar angle θ is referred to as the surface normal.

nearly complete inversion of the Mn monolayer can be obtained by direct sequential deposition of 0.9 ML Mn and Ag at 80 K and subsequent annealing at 300 K to improve atomic order. As can be seen in Figure 1, the relevant XPD profile closely resembles the one obtained upon deposition at RT. Yet the anisotropy A is now as large as 32% and the surface composition close to a pure Ag layer. Hence, a nearly perfect Ag/Mn/Ag(100) structure is grown in this way. This structure shows a sharp $p(1 \times 1)$ LEED pattern and, according to XPD, remains stable up to ≈ 350 K. At higher temperature the Mn atoms tend to move into deeper atomic layers of the Ag(100) substrate.

To gain more insight into the stability of Mn/Ag(100) films, we have performed *ab initio* calculations for the following systems: (1) Mn (1 ML)/Ag(100), (2) Ag (1 ML)/Mn(1 ML)/Ag(100), and (3) $\text{Mn}_{0.5}\text{Ag}_{0.5}$ (2 ML)/Ag(100). These calculations simulate the experimental process of the

Mn growth on Ag(100), if the Mn film evolves from an on-top ML on Ag(100) to an inverted ML covered by a Ag plane, through a MnAg alloy formation. In the case of a MnAg alloy, we consider the simple case where one has a 2-ML-thick epitaxial MnAg alloy with a $c(2 \times 2)$ structure, which keeps the fcc lattice of Ag(100) substrate. We apply the tight-binding linear muffin-tin^{6,7} method in the atomic-sphere approximation, together with the local spin-density approximation of von Barth and Hedin.⁸ The ultrathin films for situations (1), (2), and (3) are, respectively, modeled by $\text{Mn}_1/\text{Ag}_7/\text{Mn}_1$, $\text{Ag}_1/\text{Mn}_1/\text{Ag}_5/\text{Mn}_1/\text{Ag}_1$ and $[\text{Mn}_{0.5}\text{Ag}_{0.5}]_2/\text{Ag}_5/[\text{Mn}_{0.5}\text{Ag}_{0.5}]_2$ slabs, using the supercell technique. All nonmagnetic and magnetic calculations are performed taking into account the $c(2 \times 2)$ unit cell containing two atoms per layer and using the experimental lattice constant of Ag ($a_{\text{Ag}}^{\text{exp}} = 7.73$ a.u.). For the k -space integration, we use the tetrahedron method^{9,10} and an increasing number of k points, until convergence is obtained. Total energy convergence is assumed with an accuracy better than 10^{-5} Ry.

In order to investigate the energetic stability of an on-top Mn ML against the formation of an inverted Mn ML, we compare the total energy $E_{(1)}$ of 1 ML of Mn deposited on Ag(100), with the total energy $E_{(2)}$ of a Mn ML covered by a Ag layer. The energy differences $\Delta E_{(2)-(1)} = E_{(2)} - E_{(1)}$ for nonmagnetic (NM), ferromagnetic (FM), and antiferromagnetic (AFM) Mn films are reported in Table II. Regardless of the magnetic state of the Mn films, we find that $\Delta E_{(2)-(1)}$ has negative values, which means that the situation (2), where Mn atoms form an inverted ML, is the energetically preferred state. The role which magnetism plays in modifying the stability of Mn films is elucidated by comparing the magnetic (FM and AFM) calculations with the NM one. The effect of magnetism appears with a large reduction ($\approx 50\%$) of $\Delta E_{(2)-(1)}$, which means that magnetism acts against interdiffusion and tends to stabilize the Mn ML film on the Ag(100) substrate. Of course, it should be kept in mind that the usual driving forces for layer inversion and interdiffusion such as atomic size mismatch, relative heteroatomic and homoatomic bond strengths¹¹ play a major role in this system too. Yet we find that the Mn case is a special one where magnetism makes a large unusual contribution to the total energy of surface atomic configurations. The magnetic energy gain for the FM state (22.5 mRy/Mn atom) is lower than for the AFM one (26.75 mRy/Mn atom), indicating that the long range magnetic order of the Mn films contributes to the strength of the magnetism effect on the stability of the magnetic films. The main effect, however, remains the for-

mation of large local magnetic moments on Mn atoms, roughly $4 \mu_B$ for all structures (see Table III).

As to the magnetic structure of the Mn film, we compare the total energy $E_{(FM)}$ of the FM film with the total energy $E_{(AFM)}$ of the AFM one in the two structural situations. The energy differences $\Delta E_{(FM)-(AFM)} = E_{(FM)} - E_{(AFM)}$, together with the Mn magnetic moments, are reported in Table III. Interestingly, we find that the magnetic structure of Mn ML film depends on the coordination number of its constituent atoms with respect to Ag atoms. While it is known from previous works,¹² as well as the present one, that a Mn ML film on Ag(100) is predicted to be $c(2 \times 2)$ AFM, the inverted Mn ML prefers the $p(1 \times 1)$ FM structure. Experimentally, we generally observe a sharp $p(1 \times 1)$ LEED pattern in 20–400 eV range but with a weak $c(2 \times 2)$ superstructure, at primary energies below 100 eV, for the flat Mn ML on Ag(100) obtained by deposition at 80 K. This superstructure is attributed to inplane AFM order and found to be definitely absent for the inverted ML in the 80–350 K range.¹³ These observations are consistent with the present calculations but cannot rule out the possibility that the inverted layer is still inplane AFM below 80 K, i.e., coating with a Ag top layer merely reduces the Néel temperature below 80 K.

We have also investigated the case of MnAg-alloy formation for a better understanding of the growth mode of Mn films on the Ag(100) substrate. The MnAg alloy is modeled by a 2-ML-thick $c(2 \times 2)$ MnAg alloy on top of Ag(100), where every second Mn atom is substituted by a Ag atom in a checkerboard type monolayer. In Table II, we report the results of the energy differences $\Delta E_{(3)-(1)}$ and $\Delta E_{(2)-(3)}$, respectively, between the total energy $E_{(3)}$ of the MnAg alloy on Ag(100) and the total energies of the two other structural configurations, $E_{(1)}$ and $E_{(2)}$, respectively. The negative values of these energy differences means that MnAg-alloy formation is energetically preferred to 1 ML of Mn

deposited on top of Ag(100), and energetically prohibited to the formation of an inverted Mn ML. This is in agreement with the experimental observation of the alloy formation in the two topmost layers of the sample, immediately after Mn deposition, and the further Mn/Ag atoms exchange, increasing the Mn concentration in the second atomic plane of the sample.

To summarize, we have shown that Mn monolayer on top of Ag(100) is unstable at RT. A MnAg superficial alloy is formed in the two topmost atomic layers, immediately after Mn deposition. Moreover, the Mn incorporation in the second plane is thermally activated, and an inverted Mn layer tends to be formed by mild annealing. Eventually, the completely inverted ML remains stable up to 350 K. These experimental findings are in line with our electronic band structure calculations, which show that the inverted Mn layer constitutes the energetically preferred state as compared to a MnAg alloy formation or to a Mn monolayer on top of Ag(100). Moreover, the calculations show that magnetism acts against interdiffusion and tends to stabilize the Mn monolayer film on top of Ag(100), but not to the extent to prevent the formation of an inverted Mn layer at RT or above. As to the magnetic structure of the inverted Mn ML, we find that the $p(1 \times 1)$ FM order is energetically preferred to the $c(2 \times 2)$ AFM one.

The stability of a MnAg surface alloy was investigated employing the total energy and atomic force full-potential linearized augmented plane wave method based on the local density approximation for: (i) a clean Ag(001), (ii) 1 ML Mn overlayer [1 Mn/Ag(001)], (iii) 1 and 2 ML MnAg alloys as overlayers on Ag(001) [1(MnAg)/Ag(001) and 2(MnAg)/Ag(001)], and (iv) 1 ML Mn diffused into Ag(001) substrate [Ag/1 Mn/Ag(001)]. Results obtained show that 2(MnAg)/Ag(001) is much more stable than 1 Mn/Ag(001) (by a large energy difference of 150 meV), whereas 1(MnAg)/Ag(001) is marginally more stable (by a slight energy difference of 8 meV) compared to a separate phase of Ag and Mn atoms. Surface Mn and subsurface Mn atoms in 2(MnAg)/Ag(001) were found to be coupled antiferromagnetically with magnetic moments of 3.96 and $-3.55 \mu_B$, respectively. The surface corrugation ($\Delta z = 0.05$ a.u.) of 2(MnAg)/Ag(001) was found to be much smaller than that ($\Delta z = 0.5$ a.u.) of another magnetically stabilized surface alloy system, MnCu/Cu(001). No significant magneto-optical effects for antiferromagnetic Ag/Mn/Ag(001) were found due to the small off-diagonal elements of the optical conductivity. © 1998 American Institute of Physics. I. INTRODUCTION

It has been known that an alloy could have a different chemical composition at a surface from that of its bulk, with new physical properties which cannot be seen in bulk. In addition to alloy surfaces, surface alloys can be synthesized by depositing one material on the surface of a second metal and subsequent annealing.¹ Further, surface alloys phases may not be found in bulk and so may provide new desirable physical properties not seen in a bulk.

While different surface alloys could be stabilized by different mechanisms, it has been reported that the enhanced ferromagnetic magnetic moment ($\sim 3.65 \mu_B$) at the surface plays an important role in stabilizing the surface alloy of MnCu on Cu(001).²

Recently, some very interesting results were also obtained for Mn atoms grown on an Ag(001) surface. A prominent $c(2 \times 2)$ low-energy electron diffraction (LEED) pattern was observed when one monolayer (ML) dosage of Mn atoms is deposited on Ag(001) at room temperature, whereas only a diffuse $c(2 \times 2)$ LEED pattern was observed for a half-ML dosage. The prominent LEED pattern was confirmed with LEED current-voltage ($I-V$) analysis to be best fitted to a 2 ML MnAg surface alloy on an Ag(001) substrate [2(MnAg)/Ag(001)].³

We report on first principles calculations done to give some physical informations on the formation of a MnAg surface alloy. Employing the full-potential linearized augmented plane wave (FLAPW) method,⁴ the atomic structure of the MnAg surface alloy was determined from total energy and atomic force calculations for clean Ag(001), 1(MnAg)/

Ag(001), 1 Mn/Ag(001), Ag/1 Mn/Ag(001), and 2(MnAg)/Ag(001). In addition to the magnetic moments, we also calculated the optical conductivity tensor and the polar Kerr angles for Ag/1 Mn/Ag(001) (which turns out to be energetically the most stable system) and also for a free standing Mn monolayer and a Mn bulk with Ag lattice constants.

II. METHOD

To investigate the atomic structure of Mn atoms grown on Ag(001), we calculated total energies and atomic forces⁵ of the system, employing the FLAPW method. Single slabs composed of seven layers in total were employed and the two dimensional unit cell was taken with two atom types per layer to accommodate the $c(2 \times 2)$ structure observed in LEED.³

The local density Kohn-Sham equations⁶ are solved self-consistently using the FLAPW method with about 1400 basis functions and 15 special k points within the irreducible 2D Brillouin zone. Self-consistency is assumed when the average root mean square differences between input and output charge and spin densities are less than $1 \times 10^{-4} e/(a.u.)^3$ and the total energy is stable to within 0.02 mRy. The lattice constant ($a = 7.58$ a.u.) obtained from calculations for bulk Ag with the same method is adopted for the 2D lattice constant of the Ag substrate. A relaxed structure is assumed to be found if the atomic forces are less than 1.5 mRy/a.u.

For the polar surface magneto-optical Kerr effect (SMOKE) calculation, we treated the spin-orbit coupling (SOC) in a second variational method⁷ without spin-flip contributions by neglecting the off-diagonal elements of the SOC matrix. For the optical conductivity tensor the interband transitions were calculated with linear response theory.⁸ We

TABLE I. Total energies (eV) of 1 Mn/Ag(001), 2(MnAg)/Ag(001), and Ag/1 Mn/Ag(001) in paramagnetic (PM), ferromagnetic (FM), and antiferromagnetic (AFM) phases referred to that of 1 Mn/Ag(001) in the PM state.

System	Total energy (eV)		
	PM	FM	AFM
1 Mn/Ag(001)	0.0	-1.53	-1.60
2(MnAg)/Ag(001)	-0.25	-1.64	-1.75
Ag/1 Mn/Ag(001)	-0.72	-1.94	-1.96

did not include the intraband contribution (which contributes in the low energy region below 2 eV)⁹ which is usually done by adding the Drude term to the diagonal conductivity elements, due to the difficulty of finding the Drude lifetime and conductivity for the various environments used. We introduced finite lifetime broadening effects by using a Lorentzian corresponding to a life time parameter, τ (taken as 0.41 eV), to calculate the optical conductivity elements. Then the complex Kerr angle is obtained by Fresnel's law.¹⁰

III. RESULTS

A. Atomic structure: Total energy and atomic force calculations

Relaxed structures of our systems were determined from minimization of the total energy and absolute values of the atomic forces. To determine the stability of the MnAg surface alloy, we first calculated the total energies of the fully relaxed Ag(001), 1 Mn/Ag(001), and 1(MnAg)/Ag(001) and compared the total energy ($TE_{1 \text{ (MnAg)/Ag}}$) of ML MnAg surface alloy to the average of the total energies of a clean Ag(001) (TE_{Ag}) and ML Mn on Ag(001) ($TE_{1 \text{ Mn/Ag}}$). The difference, $TE_{1 \text{ MnAg/Ag}} - \frac{1}{2}(TE_{\text{Ag}} + TE_{1 \text{ Mn/Ag}})$, was found to be small, about -8 meV. This indicates that the ordered MnAg surface alloy ML is energetically slightly more stable compared to a separate existence of Ag and Mn layers, but this may not be observable at room temperature, and may explain why the distinct $c(2 \times 2)$ LEED pattern was not observed in the experiment when a half-ML of Mn atoms was deposited on Ag(001).

Table I shows the total energies of 1 Mn/Ag(001), 2(MnAg)/Ag(001), and Ag/1 Mn/Ag(001) in different magnetic states, i.e., paramagnetic (PM), ferromagnetic (FM), and antiferromagnetic (AFM), referred to that of 1 Mn/Ag(001) in the PM state. In these calculations, the average interlayer spacing of bulk Ag and Mn were used for those of Mn-Ag and MnAg-Ag with no allowance for relaxation. Since the relaxation energy is of order 10 meV and the energy differences among magnetic states and atomic structures are of order 100 meV, any conclusions from these calculations should not be changed by including relaxation. As shown in Table I, AFM states are found to be the most stable compared to PM and FM states for all three systems: 2(MnAg)/Ag(001) is much more stable compared to 1 Mn/Ag(001), by 150 meV, which is the reason why a prominent $c(2 \times 2)$ LEED pattern was observed in the experiment when the dosage of Mn atoms is 1 ML.³ Furthermore, Ag/1 Mn/Ag(001) is the most stable among the three systems so that

TABLE II. Magnetic moments (μ_B) of Mn atoms in 1 Mn/Ag(001), Ag/1 Mn/Ag(001), 1(MnAg)/Ag(001), and 2(MnAg)/Ag(001).

System	Magnetic moments (μ_B)	
AFM 1 Mn/Ag(001)	3.94	
AFM Ag/1 Mn/Ag(001)	3.73	
FM 1 (MnAg)/Ag(001)	4.16	
AFM 2(MnAg)/Ag(001)	S	3.96
	S-1	-3.55

Ag surface segregation would occur when the system is annealed. This also agrees with experiment where an analysis of the LEED $I-V$ curve indicated diffusion of Mn into the Ag substrate with annealing.³

For 1(MnAg)/Ag(001), surface corrugation ($\Delta z_S = z_{\text{Ag}} - z_{\text{Mn}} \approx 0.02$ a.u.) in the FM phase was found to be negligible whereas a significant corrugation ($\Delta z_S \approx +0.4$ a.u.) was found in the PM phase. By comparison, the results for 1(MnCu)/Cu(001)² show corrugation (Δz_S) to be -0.5 a.u. and almost zero for the FM and PM phases, respectively. Our results come from the 13% larger atomic radius of Ag compared to that of Cu. As found from total energy calculations for 1 Mn/Ag(001),¹¹ AFM coupling results in a larger interlayer spacing (by 0.03 a.u.) compared to FM coupling. Even though we did not calculate which magnetic state would be more stable in 1(MnAg)/Ag(001) (since allowing AFM coupling requires four atom types per layer and much more computing time), AFM coupling between Mn atoms might result in further reduced corrugation. Noting that the atomic radius of Mn is much smaller than that of Ag, this result is very interesting and may be explained by magnetic pressure due to the greatly enhanced magnetic moment ($4.16 \mu_B$) of Mn in the surface alloy compared to those (1.84 or $1.75 \mu_B$, depending on atom type)¹² of bulk Mn.

For 2(MnAg)/Ag(001) in the AFM ground state, somewhat larger corrugations ($\Delta z_S = +0.05$ and $\Delta z_{S-1} = -0.098$ a.u.) were calculated.

B. Magnetism

Magnetic moments of Mn atoms in relaxed AFM 1 Mn/Ag(001), Ag/1 Mn/Ag(001), 2(MnAg)/Ag(001), and FM 1(MnAg)/Ag(001) are presented in Table II. As mentioned in the previous section, AFM couplings between neighboring Mn atoms in 1 Mn/Ag(001), Ag/1 Mn/Ag(001), and 2(MnAg)/Ag(001) are found to be more stable compared to the FM couplings. The magnetic moments are calculated to be 3.94, 3.73, and $4.16 \mu_B$ for Mn atoms in 1 Mn/Ag(001), Ag/1 Mn/Ag(001), and 1(MnAg)/Ag(001), and 3.96 and $-3.55 \mu_B$ for Mn(S) and Mn(S-1) atoms in 2(MnAg)/Ag(001), respectively. The magnetic moments are much more enhanced compared to experimental values in bulk Mn.¹³ The magnetic moment ($4.16 \mu_B$) of the monolayer MnAg surface alloy [1(MnAg)/Ag(001)] is gigantic, corresponding to the almost fully magnetized value due to the large distance between Mn atoms and the small band hybridization between Mn and Ag atoms. This value is larger than those (3.75 and $3.5 \mu_B$, respectively)² of 1 MnCu/Cu(001) and 1 MnNi/Ni(001) by 11% and 19%, respectively.

FIG. 1. Complex Kerr angles, (a) rotation ϕ and (b) ellipticity ϵ for: FM Mn bulk (thick solid), FM (thick dashed) Mn free standing monolayer, and AFM Ag/Mn/Ag(001) (thin dotted). All systems have the Ag lattice constant. In the AFM Mn free standing ML case the results are so small [essentially zero as in the AFM Ag/Mn/Ag(001) case] to not show up in these plots.

C. Smoke

We calculated the MOKE for (i) AFM Ag/1 Mn/Ag(001) which is the most stable system compared to 1 Mn/Ag(001) or 2(MnAg)/Ag(001), (ii) FM and AFM Mn free standing ML, and (iii) FM Mn bulk with the same (Ag) lattice constant. The results are shown in Fig. 1. For AFM systems we obtained negligible MOKE angles compared to those of FM systems, due to their small off-diagonal conductivity elements, σ_{xy} . The finite value of σ_{xy} which is crucial for the magneto-optical effects results from the spin-orbit coupling and the exchange splitting. As pointed out by Erskine and Stern,¹⁴ the imaginary part of the off-diagonal conductivity elements, $\sigma_{xy}^{(2)}$, which measures the difference in absorption of the right and left circularly polarized light, vanishes if either the spin-orbit coupling or the exchange coupling is switched off since the spin up and spin down contributions cancel each other. This cancellation will also occur in AFM from the contribution of atoms with opposite magnetic moments and, as a result, the off-diagonal elements of conductivity are negligibly small compared to the diagonal elements.

Figure 1 shows that there is a significant surface effect on MOKE; the MOKE angles for FM ML Mn and for bulk Mn are totally different. We found that the surface effect mainly influences σ_{xy} and this influence is reflected in MOKE; the peak positions exhibited in the MOKE angles in Fig. 1 coincide well with those that occur in σ_{xy} . However, the diagonal conductivity, σ_{xx} , shows similar behavior for both ML and bulk Mn (except for different magnitudes).

We also found that different peak positions in the absorptive part of the diagonal conductivity, $\sigma_{xx}^{(1)}$, are well explained by the change of density of states (DOS) for d

bands due to different environment and magnetic ordering. For example, a large absorption peak was observed around the energy region of 2 eV (3 eV) for AFM Ag/Mn/3 Ag (AFM ML) in which the extremely narrow spin down d bands lying around 2 to 3 eV (3 to 4 eV) below E_F gives a large peak in the density of states (DOS).

IV. CONCLUSIONS

The bilayer MnAg surface alloy on Ag(001) is much more stable energetically compared to a Mn monolayer on Ag(001) by about 150 meV whereas the monolayer MnAg surface alloy is slightly more stable compared to the separation of Mn and Ag atoms at the surface. These facts are consistent with recent experiments which observed bright $c(2 \times 2)$ LEED spots for a bilayer MnAg surface alloy and dim LEED spots for the monolayer. The surface corrugations (0.02 and 0.05 a.u.) of 1(MnAg)/Ag(001) and 2(MnAg)/Ag(001) was found to be much smaller than that (0.5 a.u.) of a MnCu surface alloy on Cu(001)—also in agreement with experiment. The magnetic moments were calculated to be 4.16, 3.96, and 3.55 μ_B for Mn(S) in MnAg(001), and Mn(S) and Mn(S-1) in 2(MnAg)/Ag(001).

We found no significant magneto-optical effects for AFM Ag/1 Mn/Ag(001) due to the small off-diagonal elements of the optical conductivity compared to the diagonal elements. The conductivity elements were largely influenced by the change of the d band density of states caused by surface effects and different magnetic ordering.

Artificial FeCu(100) epitaxial ordered alloy films: Element-selective magnetic properties

W. Kuch,^{a)} M. Salvietti, Xingyu Gao, M. Klaua, J. Barthel, Ch. V. Mohan, and J. Kirschner

Max-Planck-Institut für Mikrostrukturphysik, Weinberg 2, D-06120 Halle, Germany

Epitaxial artificial FeCu alloy thin films in the fcc $L1_0$ ordered phase were prepared by pulsed laser deposition on Cu(100). Magnetic circular dichroism in x-ray absorption at the Fe and Cu $L_{2,3}$ edges was used to study the electronic and magnetic properties of the normally immiscible FeCu(100) alloy films. The Fe exhibits magnetic moments comparable to that of fcc Fe films, ruling out the occurrence of nonmagnetic fcc Fe. The ratio between orbital and spin contribution to the Fe d moments is significantly enhanced in FeCu with respect to Fe/Cu(100), and amounts to ≈ 0.12 . An induced magnetic moment of the Cu atoms is observed, which carries about 7% of the total d -band moment of the FeCu film. © 1998 American Institute of Physics. [S0021-8979(98)48011-3]

Magnetic artificial alloys have not yet been subject to investigations concerning their element-selective magnetic properties. Artificial alloys of the otherwise immiscible elements Fe and Cu have been synthesized mechanically in the bulk by ball milling techniques^{1,2} as well as by sputtering.^{3,4} It was reported that for Fe concentrations below $\approx 70\%$ the fcc structure is assumed, and for higher Fe concentrations the bcc structure.^{2,3} In contrast to these techniques we use pulsed laser deposition to stabilize the fcc phase of epitaxial artificial FeCu alloy thin films on Cu(100). The films grow in a layer-by-layer mode already starting with the first layer, as judged by reflection high energy electron diffraction during growth.⁵ Subsequent deposition of monoatomic layers of Fe and Cu results in the $L1_0$ ordered phase of FeCu. These films exhibit an easy axis of magnetization in the film plane.⁵ Scanning tunneling microscopy investigations show a degree of layer perfection better than 98% per deposited FeCu bilayer.⁵ Spin-resolved valence band photoemission measurements revealed bands which are present due to the reduced size of the alloy Brillouin zone perpendicular to the film plane.⁶ This reflects the doubling of the unit cell in the ordered alloy with respect to pure Cu or Fe, and additionally proves the structural quality of our stacked samples.

In this contribution we report results of magnetic circular dichroism in soft x-ray absorption (XMCD) measurements of these fcc FeCu alloy films. XMCD probes the spin asymmetry of the unoccupied part of the band structure just above the Fermi level. The dichroism, i.e., the difference in absorption cross section upon reversal of the magnetization direction, depends on the transition probability for spin-up and spin-down electrons into the mainly minority type unoccupied bands, and constitutes an element selective measure of magnetic and electronic properties.⁷ Sum rules^{8,9} allow under some assumptions to extract the elementally resolved spin and orbital magnetic moments from the experimental absorption spectra.

Films of 10 atomic layers (monolayers, ML), alternately consisting of Fe and Cu, were deposited by pulsed laser

deposition at room temperature on a Cu(001) substrate. A cap layer of 3 ML Au was evaporated on top for protection against residual gases. After preparation of the samples, which was done at the laboratory in Halle, the samples were transferred under ultrahigh vacuum (UHV) conditions to the Berlin synchrotron radiation source (BESSY). During the transport a pressure of about 4×10^{-8} Pa was maintained in the transfer chamber. The typical time interval for transfer and transport elapsed between the preparation of the samples and the beginning of the measurements at BESSY was about 4 h.

XMCD measurements were performed at a sample temperature of 120 K. The sample was remanently magnetized along the in-plane [110] direction by ramping the current through a coil. The magnetization procedure was monitored by magneto-optical Kerr effect, as was the presence of the remanence before and after each scan of data acquisition.

Absorption spectra were taken at the PM-3 beamline at BESSY. The photon energy resolution was ≈ 1.5 eV in the region of the Fe and Cu L edges. Circularly polarized x rays were obtained by selecting light from 0.3 mrad below the ring orbit. Measurements of Co reference films yielded an estimate of about 40% for the degree of circular polarization in that configuration. The total electron yield was recorded by measuring the sample drain current with a bias voltage of -27 V applied. The sample magnetization was reversed after each energy scan. The 8 or 10 scans at the Fe L edge, and between 40 and 60 at the Cu L edge were summed up. The spectra were normalized to the current of a gold grid monitor located just behind the exit slit of the monochromator, and corrected for the angle of light incidence of 45° and the estimated degree of circular polarization. The analysis of the Fe $L_{2,3}$ absorption spectra was done as outlined in Ref. 10 or 11. In particular, the spectra were normalized to unity edge jump, and two step functions of 0.5 eV width and $2/3(1/3)$ height at the $L_3(L_2)$ absorption maxima were subtracted. A constant number of Fe $3d$ holes of 3.34 was assumed.¹² The Cu $L_{2,3}$ spectra were analyzed by comparing them to the spectra of Ref. 13, taking into account the different angle of incidence and the different degree of light polarization in our

^{a)}Electronic mail: kuch@port.exp.bessy.de

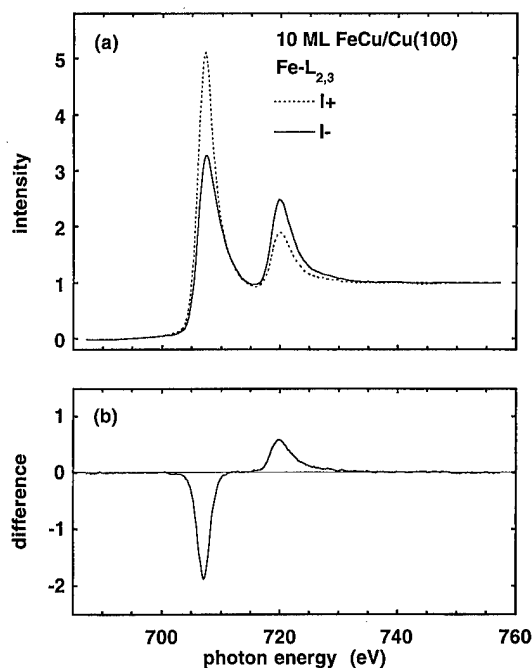

FIG. 1. (a) Absorption spectra at the Fe $L_{2,3}$ edge of a 10 ML FeCu film for parallel (dotted line) and antiparallel alignment of magnetization direction and light helicity (solid line). (b) Difference between the spectra of (a).

experiment. In this way the value for the ratio of white line intensity to number of d holes for Cu of Ref. 13 is used, and it is not necessary to integrate the Cu absorption intensity.

Absorption spectra at the Fe- $L_{2,3}$ edge are shown in Fig. 1(a). Spectra for parallel and antiparallel alignment of magnetization direction and light helicity are reproduced by dotted and solid lines, respectively. The difference between the two spectra is plotted in Fig. 1(b). A strong dichroism is observed with negative (positive) peaks at the L_3 (L_2) edges. The sum rule analysis of the data yields a spin moment of $1.8 \pm 0.06 \mu_B$, and a ratio of orbital to spin moment of 0.12 ± 0.03 .

Measurements under identical experimental conditions of 3.5 ML fcc Fe/5 ML Co/Cu(100) films, which are entirely ferromagnetically ordered,¹⁴ resulted in a similar spin moment of $1.9 \pm 0.1 \mu_B$, and also in a similar (within 5%) white line intensity.⁶ The cited errors represent the accuracy and reproducibility of the measurements, and do not include systematic errors due to uncertainties in the exact degree of circular polarization, the number of $3d$ holes, or the details of the steplike background subtracted for white line integration. They are, however, appropriate for comparing results obtained from different samples under identical experimental conditions. Comparing the results from the FeCu alloy and the Fe/Co reference film, we conclude that all of the Fe atoms in the FeCu alloy film carry a moment close to that of fcc Fe. In the sum-rule analysis the contribution of the magnetic dipole term⁹ to the spin moment is usually neglected, a variation of which may introduce an additional error of up to 10%.¹⁵ The ratio μ_L/μ_S between the orbital and spin moment, nevertheless, is significantly enhanced in the FeCu film, being about a factor of 3 larger than in the 3.5 ML Fe film (0.04 ± 0.01).⁶ Increased orbital moments have been ob-

FIG. 2. (a) Absorption spectrum at the Cu $L_{2,3}$ edge of a 10 ML FeCu film, averaged over antiparallel and parallel alignment of magnetization direction and light helicity. The inset shows a sketch of the film architecture. (b) Absorption difference between antiparallel and parallel alignment of magnetization direction and light helicity at the Cu $L_{2,3}$ edge. Note the different vertical scale with respect to (a).

served previously in films of decreasing thickness,¹⁶ and have been discussed in terms of higher density of states at the Fermi level,^{16,17} and magnetic anisotropy.^{15,18} We tentatively conclude the observed orbital moments as a consequence of the ordered layer stacking, reflecting the electronic structure of the FeCu films.

Figure 2(a) shows the absorption spectrum of FeCu at the Cu $L_{2,3}$ edge. Here, the average absorption for both magnetization directions is reproduced rather than the individual curves, because the difference between these is much smaller than at the Fe $L_{2,3}$ edge, and would not be reproduced clearly on the scale of Fig. 2(a). This is seen from Fig. 2(b), where analogously to Fig. 1(b) the difference in absorption between antiparallel and parallel alignment of magnetization direction and light helicity at the Cu $L_{2,3}$ edge, corrected for the angle of light incidence and the estimated degree of circular polarization, is reported. Note the vertical scale, which is blown up by an (arbitrary) factor of 10 with respect to Fig. 2(a). A small but distinct dichroism at the energetic positions of the Cu L_3 and L_2 edges with the same sign as at the respective Fe edges is observed. It amounts to about -4% and $+2\%$ of the Cu edge jump height. A magnetic moment is thus present at the Cu atoms, introduced by the presence of the Fe atoms.

Applying the sum rules to the spectra of Fig. 2 yields Cu atomic spin moments of $0.05 \pm 0.005 \mu_B$. Before comparing this value to other systems, it has to be considered though that by measuring the absorption by the total electron yield there is still a significant contribution from the Cu(100) substrate to the Cu absorption signal at the thickness of the FeCu films (10 ML). For a mean free path of 11 ML ($\approx 20 \text{ \AA}$) the Cu signal stems to about 55% from the substrate. Assuming

that the substrate atoms do not show any magnetic dichroism, $\mu_S = 0.12 \pm 0.01 \mu_B$ is obtained for the Cu atoms in the FeCu film. Comparing that to the Fe atomic moment it is found that about 7% of the *d*-band magnetic moment of the FeCu film is carried by the Cu atoms.

The induced Cu magnetic moments are higher than those observed in Co/Cu multilayers ($0.05 \mu_B$)^{13,19} or Fe/Cu multilayers (up to $0.09 \mu_B$, depending on the Cu layer thickness),¹⁹ but comparable to Co₉₀Cu₁₀ films ($0.13 \mu_B$).^{13,19} Theoretical calculations for Cu induced moments in Fe/Cu multilayers yielded values of 0.07,²⁰ 0.05,²¹ and $0.06 \mu_B$.²² For a layered FeCu alloy similar to the one investigated here the resulting theoretical moment was $0.08 \mu_B$.²² This is slightly lower than what we observe experimentally, but has the right order of magnitude. It is conceivable that details in which the geometric structure assumed for the calculations differs from the structure realized in the FeCu samples may account for the differences between theory and experiment.

In conclusion, we have investigated ultrathin epitaxial fcc FeCu ordered alloy films on Cu(100). Element selective electronic and magnetic properties were obtained by XMCD at the Fe and Cu *L*_{2,3} edges. Induced moments of the Cu atoms, which amount to about 6% of that of the Fe moments, and increased Fe orbital moments were found. The findings are attributed to the modification of the electronic structure due to hybridization between Fe and Cu derived states, the reduced symmetry along the surface normal, and altered dimensionality in the layered alloys.

Orbital magnetic moment enhancement at surfaces and interfaces within the framework of the local density approximation+ U method

Stimulated by MCXD measurements, the determination of orbital magnetic moments, M_L , at surfaces and interfaces has become a subject of strong interest. We combine the rotationally invariant local density approximation (LDA)+ U total energy functional with a relativistic self-consistent spin-polarized version of the total energy full-potential linearized augmented plane wave method in order to determine M_L at surfaces and interfaces. As illustration, the method is applied to Co overlayers on Cu(001). We find an enhancement of the Co orbital magnetic moment in LDA+ U calculations in comparison with local spin density functional approximation (LSDA) results. M_L as a function of magnetic Co-film thickness is analyzed. The M_L/M_S ratio is calculated to be different for different Co layers (i.e., interface, surface, or remaining Co layers) in Co/Cu(001), and is shown to be dependent on the Co overlayer thickness. Finally, the use of LDA+ U is shown to give M_L/M_S in better agreement with MCXD data than does LSDA. © 1998 American Institute of Physics. [S0021-8979(98)37611-2]

First principles electronic structure calculations of transition metal surfaces and ultrathin films¹ show that there is a significant enhancement of spin and orbital magnetic moments at the surface in comparison to their bulk values. The enhancement of the spin moment, which is caused by reduced coordination of the surface atom due to symmetry lowering, is accompanied by an enhancement of the orbital magnetic moment. However, calculations¹ which are based on the local spin density functional approximation (LSDA) do not provide a complete description for orbital magnetic moments even for the case of bulk transition metal ferromagnets.² Now, within LSDA spin-orbit coupling (SOC) is the only effect considered responsible for orbital magnetization and other sources, namely noncentral field contributions to the electron–electron interaction³ and orbital current polarization,⁴ are neglected.

We examine the influence of electron–electron interactions on M_L . It was shown very recently,³ that Hubbard mean-field exchange energy contributes to the orbital polarization (OP) differently than the so-called orbital polarization correction of Brooks (OPB).⁵ The latter is based on the intuitive analogy with atomic theory⁶ and does not take into account the Coulomb contribution U to the OP. Moreover, whereas spin and orbital polarization effects are coupled³ via the common set of Slater integrals (which are used to represent the electron–electron interaction⁷), they are treated independently in OPB.

We start from the rotationally invariant local density approximation (LDA)+ U total energy functional of the form⁷

$$E^{\text{tot}}(\rho^\sigma(\mathbf{r}), \hat{n}^\sigma) = E^{\text{LSDA}}(\rho^\sigma(\mathbf{r})) + E^{\text{ee}}(\hat{n}^\sigma) - E^{\text{dc}}(\hat{n}^\sigma), \quad (1)$$

where, E^{LSDA} is the LSDA total energy functional of spin density $\rho^{\uparrow,\downarrow}$, E^{ee} is the electron–electron interaction energy in the Hartree-Fock approximation (which depends on the

site-occupation matrix \hat{n} for the set of correlated electrons and can be obtained by projection of the electron eigen functions on a site-centered angular momentum basis set), and E^{dc} is the “double-counting” term⁷ to compensate the electron–electron energy which is included in E^{LSDA} . Further, only the d -electron contributions to E^{ee} and E^{dc} are considered, and we approximate the site-occupation matrix by its MT part only (this is a reasonable approximation for 3d-electron systems since almost all of the d -electron spin density is located within the MT sphere). Applying the variational principle then yields a set of single-particle Kohn–Sham equations, where, in addition to the usual Kohn–Sham spin-dependent potential there is a projection operator of the form $\sum_{m,m'} V_{mm'}^\sigma |Y_{lm}\rangle \langle Y_{lm'}|$ acting on the d electrons. The $V_{mm'}^\sigma$ depend on the site-occupation matrix $\hat{n}_{mm'}^\sigma$, angular matrix elements of the on-site electron–electron interaction, and a set of Slater integrals $F^{2k}(k=0,1)$ (the explicit form of $V_{mm'}^\sigma$ is given by Eq. (5) of Ref. 7).

We have combined the rotationally invariant LDA+ U and the relativistic version of the full-potential linearized augmented plane wave (FLAPW) method by making use of a second variation procedure:⁹ first, scalar-relativistic wave functions are determined within the conventional FLAPW method with the LSDA effective potential (first variation); then the LDA+ U Kohn–Sham equations are solved in the orthogonal basis of these wave functions (only the MT contributions in the LDA+ U Hamiltonian are considered); finally new second variation eigen functions are used to solve the relativistic Kohn–Sham–Dirac equations (with spin-orbit coupling included)¹⁰ and the self-consistent ground state charge and spin densities and site-occupation matrices are obtained.

TABLE I. Layer by layer resolved spin M_S and orbital M_L magnetic moments and their ratio, $R_{LS}=M_L/M_S$, for the Co_n ($n=1,2,3$) overlayers (labeled from the top layer) for different values of U (eV) and $J=1$ eV in comparison with the LSDA results.

Layer		LSDA	$U=1$	$U=1.5$	$U=2$

Co ₃	R_{LS}	0.054	0.066	0.071	0.076

As an illustrative example, we used a slab model consisting of five Cu substrate layers covered by n ($n=1,2,3$) Co overlayers on each side. The ideal fcc structure with a bulk Cu lattice constant ($a=6.83$ a.u.) is assumed. The special k -points method is used for the two-dimensional Brillouin zone (2DBZ) integrations and 55 k points in the irreducible part of the BZ are employed for the self-consistent calculations with the magnetization assumed to be perpendicular to the film and a Gaussian broadening is used for weighting the eigen states. Lattice harmonics with angular momentum l up to eight are used to expand the charge and spin densities and wave functions within the muffin-tin sphere. More than 70 plane waves per atom/spin are used as the first variational basis set to solve the scalar-relativistic Kohn-Sham equations; all occupied and empty states up to 1 Ry above E_F are used as a second variational basis set.¹¹ Self-consistency is achieved to within $5 \times 10^{-5} e/(\text{a.u.})^3$ for charge and spin densities.

The total Coulomb interaction matrix for d electrons is defined by F^0 , F^2 , and F^4 Slater integrals. In principle, they could be linked to the Coulomb (U) and exchange parameters (J) obtained from the LSDA.¹² The F^2 and F^4 were obtained from the value of the intra-atomic exchange $J=(F^2+F^4)/14$ which is assumed to be equal to the LSDA Stoner exchange, and the ratio $F^4/F^2=0.625$ for 3d elements.¹³ For a metallic system there is an additional problem related to dynamical screening of the U by itinerant d electrons. Therefore we choose $J=I_{\text{LSDA}}=1$ eV¹⁴ and varied $F^0(=U)$ from 1 to 2 eV.

The calculated M_L and M_S magnetic moments and their ratio, R_{LS} , for Co_n ($n=1,2,3$) overlayers on Cu for different values of U (from 1 to 2 eV) and with $J=1$ eV are presented in Table I.¹⁵ As seen from these data: (i) M_S , M_L , and R_{LS} depend on the location of the Co layer in the overlayer and on the overlayer thickness; (ii) for $U=J=1$ eV, there is practically no increase of M_S (due to the fact that $I=(U+4J)/5$ is equal to I_{LSDA} for $U=J$) but M_L is bigger in LDA+ U than in LSDA calculations and yields an enhancement of R_{LS} by orbital polarization; (iii) there is an increase

of both M_S and M_L with an increase of U , resulting in an increase of R_{LS} .

Very recent MCXD experiments¹⁶ show quite a pronounced enhancement of R_{LS} in the ultrathin Co overlayers on fcc Cu(001). In order to compare our results with experiment, we took into account the decay in intensity of the MCXD signal from Co layers lying under the surface layer.¹⁶ Then, the effective ratio is taken as¹⁶

$$R_{LS}^{\text{eff}} = \left[A(D)e^{-\mu(D-1)} + \sum_{n=3,D} B(D,n)e^{-\mu(n-2)} + C(D) \right] / \sum_{n=0,D-1} e^{-\mu n} \quad (2)$$

with $\mu=d/\lambda$, where d is the Co-Co interlayer distance, D is the Co-overlayer thickness, and $\lambda=32.14$ a.u. is the effective electron escape depth. The parameters $A(D)$, $B(D,n)$, $C(D)$ represent R_{LS} for interface, intermediate, and surface layers, respectively. In contrast to Ref. 16, we keep an explicit dependence of A , B , and C parameters on the overlayer thickness and layer position (n). The calculated values of R_{LS}^{eff} for LSDA and LDA+ U with $U=2$ eV and $J=1$ eV are given in Table II. Whereas the LSDA results deviate significantly from experiment, the LDA+ U values provide much improved quantitative agreement. The use of an overlayer thickness independent set of A , B , and C parameters in

TABLE II. The effective R_{LS} ratio for the ($n=1,2,3$) Co_n/Cu_5 as a result of LDA+ U calculations with $U=2$ eV and $J=1$ eV in comparison with the LSDA results, FP-LMTO^{a,b} calculations and experiment.^a

Layer	LDA+U	OPB ^{a,b}	LSDA	Exp. ^a
Co/Cu ₅	0.104	0.141	0.071 0.065 ^b	
Co ₂ /Cu ₅	0.080		0.060	0.105
Co ₃ /Cu ₅	0.075		0.055	0.100

^aReference 16 (an accuracy of experimental data is estimated as ± 0.005).^bReference 17.

the ultrathin film limit, as in Ref. 16, is in disagreement with the results of the present calculations (cf., Table I). Thus, there is a significant overestimation of the M_L enhancement in Ref. 16 for the ultrathin film limit which is a consequence of an oversimplified interpretation of the experimental data.

The present LSDA results for M_S and M_L for Co/Cu(001) agree quite well with the results of first principle-linear muffin-tin orbital (FP-LMTO) calculations.¹⁷ However, the LDA+ U yields an enhancement of both M_S and M_L with increase of U while OPB¹⁷ acts on M_L only. This is one of the reasons why R_{LS} in LDA+ U is smaller than in OPB. Another possible reason is that values of M_L in OPB strongly depend on the values of the Racah parameters.⁵ The spin-polarized radial wave functions are used in Refs. 16 and 17 to calculate the Slater integrals F^2 and F^4 and Racah parameters, $B=9F^2-5F^4/441$. The values of F^2 and F^4 should be consistent with the values of the Stoner exchange I (this is not shown in Refs. 16 and 17) and their overestimation may lead to an artificial enhancement of M_L .

Finally, as seen from Table I, the spin (M_S) and especially the orbital (M_L) polarizations depend significantly on U . The use of LDA+ U ⁷ instead of LSDA for calculations of M_L/M_S improves significantly the quantitative agreement with experimental data (cf. Table II) for the Co overlayers on Cu(001).

We report magnetic extended x-ray absorption fine structure (EXAFS) measurements on 30 monolayer Fe and Co films on Cu(001) substrates at $L_{3,2}$ edges. For 3d transition metals, the magnetic EXAFS at the L edges is of great interest since it probes final d states which mainly contribute to magnetism. Magnetic EXAFS oscillations were detected up to 500 eV above the edge corresponding to 11.5 \AA^{-1} in k space. Over such a large range, the long wavelength wiggles from the Fe and Co nearest neighbor backscattering and previously observed fast oscillations are clearly seen. It is shown that without using any deconvolution procedure a meaningful analysis can be performed despite an interference of L_3 and L_2 edges. In the case of Fe, experimental data are compared with multiple-scattering calculations. © 1998 American Institute of Physics. [S0021-8979(98)50211-3]

I. INTRODUCTION

The extended x-ray absorption fine structure (EXAFS) technique has contributed a great deal to determine the local atomic structure and the dynamics of adsorbates on metal surfaces.¹ The availability of circularly polarized synchrotron radiation has enabled one to add magnetic selectivity to EXAFS. The difference in spin-polarized EXAFS, i.e., magnetic EXAFS (MEXAFS), can be determined by measuring the spin-dependent absorption in the EXAFS energy range. MEXAFS has opened up a new possibility for investigating static and dynamic magnetic phenomena from a site selective point of view.²⁻¹⁴ Earlier MEXAFS experiments on the 3d transition metal K edge^{5,8-13} and on 4f rare-earth L edges^{3,5,10-13} have shown that with this technique it is possible to study magnetic short range ordering and get useful information regarding magnetic spin moments of neighboring atoms. In the case of pure 3d metals (Fe, Co, Ni), it was found that K -edge MEXAFS oscillations are primarily due to scattering from magnetic nearest neighbors.^{5,9,10,12,13} Therefore, one can distinguish between magnetic and nonmagnetic neighbors by comparing EXAFS and MEXAFS Fourier transforms. Studies at K edges, probing final p states, which are very common in EXAFS, have some disadvantages in MEXAFS. For example, in the case of 3d transition metals, MEXAFS studies at K edges provide no information about the d states which mainly contribute to magnetism and also result in a lower MEXAFS signal. However, L -edge EXAFS and MEXAFS analyses probing d states in the case of 3d transition metals may be difficult due to smaller spin-orbit splitting [13 eV (Fe), 15 eV (Co), 17 eV (Ni)] between the

L_3 and L_2 edges. This leads to an additive overlap of the (M) EXAFS spectra of the two edges, which, in the case of MEXAFS may also partly cancel the signal as the dichroic effects have the same profiles but opposite signs.

We report EXAFS and MEXAFS measurements on 30 monolayer (ML) Fe and Co films on Cu(001) substrates up to 500 eV above the $L_{3,2}$ edges. In the case of Fe, the experimental data are compared with multiple-scattering (MS) calculations.

II. EXPERIMENTAL AND DATA ANALYSIS DETAILS

Thin Fe and Co films of 30 ML thickness were grown at room temperature on Cu(001) substrates in ultrahigh vacuum (UHV) conditions and characterized by means of *in situ* low energy electron diffraction (LEED). The L -edge spectra were recorded in quasitotal electron yield mode at grazing (20°) x-ray incidence at 75 K using circularly polarized light on SX 700 monochromator beamlines at the BESSY synchrotron facility in Berlin.¹⁵

In the analysis of EXAFS, it is a well established technique to put a spline simulating the atomic background μ_0 in rough $\mu(E)$ data. Using the circularly polarized light the total absorption coefficient $\mu(E)$ in normal EXAFS can be defined as $\mu(E) = [\mu^+(E) + \mu^-(E)]/2$. Theoretically, the measured linear absorption coefficient $\mu(E)$ can be related to the fine structure $\chi(E)$ by $\mu(E) = \mu_0(E)[1 + \chi(E)]$. For the magnetic case one gets $\mu^\pm(E) = \mu_0(E)[1 + \chi(E) \pm \chi_M(E)/2]$. However, to extract magnetic information it can be derived as $\mu_M(E) = \mu^+(E) - \mu^-(E)$ and $\chi_M = \mu_M/\mu_0 = (\mu^+ - \mu^-)/\mu_0$. Throughout the text the modulations in EXAFS and MEXAFS signals are shown as χ and χ_M , respectively. Taking the difference between the right and the left polarization for MEXAFS, one may think at first glance that the background (transmission function, etc.) is

^{a)}Corresponding author. Permanent address: Department of Physics, University of Rajasthan, Jaipur 302 004, India; electronic mail: babgroup@physik.fu-berlin.de

automatically subtracted. However, it was found in the present experiments that this did not work satisfactorily because of small changes in the background. The best way found was to take the ratio deriving χ_M from μ^+/μ^- . A Taylor expansion of μ^+/μ^- around $\chi_M=0$ in first order results in $\mu^+/\mu^-|_{\chi_M=0} \approx 1 + \chi_M(1/1 + \chi)$. An approximation $(1/1 + \chi) \approx 1$ produces an error of less than 5% in the magnitude of χ_M provided $\mu^+ + \mu^- \gg \mu^+ - \mu^-$. Therefore, $1 + \chi_M \approx \mu^+/\mu^-$.

The oscillations in the extended energy regions of both EXAFS and MEXAFS of the $L_{3,2}$ edge is a combination of both edges offset by the energy separation of L_3 and L_2 edges. In k space, modulations in the EXAFS/MEXAFS signals can be expressed as $\chi(k) = \chi_{L_3}(k) + \alpha\chi_{L_3}(k + \Delta k)$. With $\chi_{L_2} = \alpha\chi_{L_3}$, $\alpha = 1/2$ for EXAFS and $\alpha = -1$ for MEXAFS. That is to say, for ferromagnets, both $\chi(k)$ and $\chi_M(k)$ oscillations contain the same basic information [nearest neighbor distances, $A(k)$, etc.]. The value of Δk steadily decreases as a function of k . For very large and very small spin-orbit splittings, α cannot be treated simply as a constant. Therefore, care has to be taken when analyzing other systems. Before starting to analyze the experimental data we checked if the superposition of the two edges hinders the analysis. This was done using *ab initio* curved wave calculations with the FEFF7S code.¹⁶ It has been shown recently¹⁷ that the superposed signal of the two edges (L_{3+2}) has a small phase shift compared to the L_3 edge. This superposition of the two edges only results in the change of intensity of various features in the Fourier transforms; their positions remain almost the same. Therefore, an analysis can be carried out on the experimental spectra containing the superposed signal of L_3 and L_2 edges. Similar results were found for EXAFS data.¹⁷ However, it was found that the effect of the superposition of L_3 and L_2 edges is more dramatic in the magnetic case. For a specific analysis of the phase relation between $\chi(k)$ and $\chi_M(k)$ it is more convenient to deconvolute L_3 and L_2 contributions. This is addressed separately.¹⁸

III. RESULTS AND DISCUSSION

Figures 1 and 2 show $k \cdot \chi(k)$ and $k \cdot \chi_M(k)$ oscillations for Fe and Co films and their corresponding Fourier transforms. Magnetic signals are normalized to $P_c = 1$ and 0° grazing incidence. Here, we would like to point out that intensities of MEXAFS signals for Fe and Co cannot be compared directly as both films have different structures. Nevertheless the ratio MEXAFS/EXAFS for the n.n. peak is higher for Fe (1:34) as compared to Co (1:40). In the case of Fe, for MEXAFS it can be seen from Fig. 1(a) that, apart from the higher frequency components, the χ_M profiles clearly show slow oscillations at intermediate and high k values. For Co the $\chi_M(k)$ profile is different. Here, the oscillations at lower k values contain information mostly from the nearest neighbor shell. This is clear if one compares the $\chi(k)$ and $\chi_M(k)$ lower k values which contain information mostly from the nearest neighbor shell. This is also clear if one compares $\chi(k)$ and $\chi_M(k)$ and their corresponding Fourier transforms (Fig. 2). At large k values higher frequency contributions can be seen. Differences in the $\chi_M(k)$ of Fe

FIG. 1. (a) The normalized EXAFS [$k \cdot \chi(k)$] (dashed line) and MEXAFS [$k \cdot \chi_M(k)$] (solid line) signals and (b) their corresponding Fourier transforms of 30 ML Fe film on Cu(001) measured at grazing x-ray incidence at 75 K.

and Co can originate from the different structures of the films and spin-orbit splitting [$\Delta E_{L_{2,3}} = 13$ eV(Fe), 15 eV(Co)]. Further analysis is in progress to draw some quantitative results.

The Fourier transforms of Fe and Co [Figs. 1(b) and 2(b)] also show distinct differences in R space. The positions of the main peaks of both elements for MEXAFS and EXAFS are not at the same distances. This is not surprising as the peak positions in the Fourier transform do not appear at the real distances but are shifted because of (M) EXAFS phase shifts which are not expected to be identical. For both elements, the MEXAFS Fourier transforms show an enhancement in the features above the main peak especially in the region between 3.5 and 5 Å. It is interesting since all neighbors probed in the magnetic and normal scattering processes are ferromagnetic. As this enhancement was more pronounced in the case of Fe, a theoretical simulation with a bcc unit cell using FEFF7S was performed. It is shown with the Fourier transform of the experimental spectrum in Fig. 3. The structure analysis of the film from the EXAFS data is discussed in detail elsewhere.¹⁷ The dashed line in the spectrum shows the simulation taking into account both single and multiple-scattering paths. It is in qualitative agreement with the experimental Fourier transform. Also, a simulation (dotted line) considering only the single-scattering (SS) paths is shown. The peak at 2.49 Å was scaled to the experiment. The main peak is a superposition of two peaks, A and

FIG. 2. (a) The normalized EXAFS [$k \cdot \chi(k)$] (dashed line) and MEXAFS [$k \cdot \chi_M(k)$] (solid line) signals and (b) their corresponding Fourier transforms of 30 ML Co film on Cu(001) measured at grazing x-ray incidence at 75 K.

B. The nearest neighbor peak A at 2.49 Å is ascribed to the SS path between atoms 1 and 2 (see the inset). Peaks B and C at 2.87 and 4.06 Å are due to SS paths between atoms 1 ↔ 3 and 1 ↔ 4, respectively. Feature D at 4.76 Å is ascribed to SS paths 1 ↔ 5. As discussed previously,¹⁷ various features between 3.5 and 5 Å in the Fourier transform of Fe showing enhancement in intensity are due to “fast” oscillations as is shown in Fig. 1(a). Therefore, the present theoretical analysis suggests that these high frequency contributions do contain appreciable amounts of SS and MS path lengths implying that the magnetic character of both single and multiple-scattering path lengths increases. However, one cannot neglect the contribution of the overlapping of the L_3 and L_2 edges in the enhancement of these features. In the case of Co, a detailed structural analysis is in progress.

A combination of a MEXAFS *ab initio* calculations with experiments leads to qualitative determination of major contributions to nearest shells from single- and multiple-scattering path lengths. Furthermore, our results show that the ratio of normal/magnetic EXAFS is at least one order of magnitude larger than previous results at K edges, i.e., approximately 34/1 and 40/1 for Fe and Co, respectively. Within the error of the experiment and theoretical models it also agrees with the different magnetic moments for the two elements.

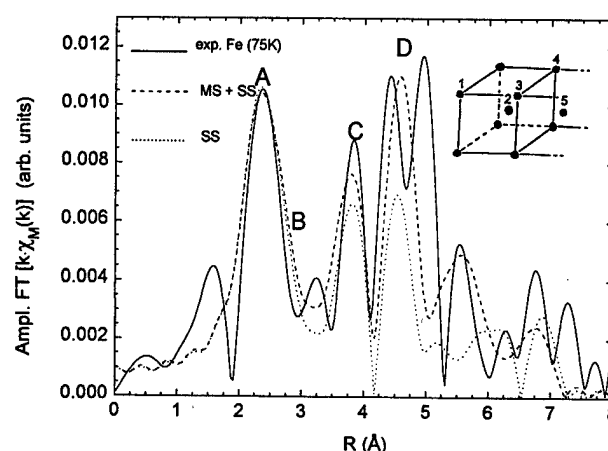

FIG. 3. Simulated Fourier transforms taking into account both multiple- and single-scattering (dashed line) paths and only single-scattering paths (dotted line) for a bcc cluster (shown in the inset) along with the experimental (solid line) MEXAFS data of 30 ML Fe film on Cu(001) recorded at grazing x-ray incidence at 75 K.

The L -edge MEXAFS as pioneered in Refs. 6 and 7 may therefore be the method of choice to study magnetic structure and dynamics from a local point of view.

We present here systematic temperature dependent magnetic extended x-ray absorption spectroscopy (MEXAFS) measurements. This fine structure can be explained by the spin dependent scattering of the photoelectron and yields information about the local magnetic surroundings of the absorbing atom. We find a strong temperature dependence at temperatures far below the Curie temperature. This shows that the intensity of the MEXAFS signal is not only determined by the value of the magnetic moment but also by the relative vibrations of the backscattering atom to the absorbing atom. © 1998 American Institute of Physics. [S0021-8979(98)50311-8]

Temperature dependent extended x-ray absorption fine structure spectroscopy (EXAFS) is a well established technique to obtain local structure and bond dynamics.¹ Recently it was shown in experimental works²⁻⁵ and in theoretical works⁶⁻⁹ that magnetic EXAFS (MEXAFS) experiments performed with circularly polarized light give insight into the spin dependent scattering of the photoelectron for ferromagnetic and anti-ferromagnetic samples. This scattering information yields the distances to the magnetic neighbors and results in a picture of the local magnetic structure which can be directly related to the local atomic structure. By probing the temperature dependence of the local magnetic disorder using magnetic EXAFS we can get a more complete picture of the magnetic behavior. This work presents a systematic investigation of the temperature dependence of the MEXAFS. We chose a polycrystalline Fe thin film of 500 Å as a model system as it is known that the Debye model describes the temperature dependence of the spin averaged EXAFS reasonably well¹⁰ although measuring at temperatures far below the Curie temperature of Fe we find an even stronger temperature dependence for the MEXAFS compared to the EXAFS. This shows that the temperature dependence of the MEXAFS is not only determined by the temperature dependence of the magnetic moment which should be constant in the temperature region investigated (70–400 K) but also by the thermal vibrations of the absorbing atom to the backscattering atom.

The helicity dependent transmission measurements in the soft x-ray regime at the $L_{3,2}$ edges had been done at the Naval Research Laboratory (NRL) facility located at the U4B beamline of the National Synchrotron Light Source (NSLS). The experimental details are reported elsewhere.^{11,12} Because of the small separation of the two edges ($\Delta E = 13.1$ eV) due to spin-orbit splitting, the recorded data represent the sum of the two edges. We show that this is not a further complication as we can model the

overlapped contributions quite well using the ab initio FEFF7 code.¹³ We measured the helicity dependent absorption coefficients $\mu^+(E)$ and $\mu^-(E)$ for right and left circularly polarized light, respectively. The spin averaged absorption defined as $\mu(E) = [\mu^+(E) + \mu^-(E)]/2$ exhibits the regular EXAFS. The EXAFS is defined by $\chi = (\mu - \mu_0)/\mu_0$ where μ is the x-ray absorption coefficient and μ_0 is the atomic x-ray absorption coefficient. Generally speaking, one has to take $p \rightarrow d$ and $p \rightarrow s$ transitions for the $L_{3,2}$ edges into account. But the $p \rightarrow s$ transitions are weak and can be neglected for our system.¹ Therefore the same analysis as is known for K edge EXAFS can be performed at the $L_{3,2}$ edges here. The magnetic signal is described by the helicity dependent absorption coefficients which exhibit a difference $\mu_m(E) = \mu^+(E) - \mu^-(E)$ which is known as magnetic circular x-ray dichroism (MCXD) for the near edge region. This difference shows a small oscillatory fine structure $\chi_m = (\mu^+ - \mu^-)/\mu_0$ in the extended energy region—the MEXAFS.

The EXAFS was analyzed in the conventional way by extracting the oscillations with a spline and normalizing the data to the edge jump. In addition to the removal of the atomic background $\mu_0(E)$ of the combined $L_{3,2}$ edges the spline function had to remove the L_1 edge. The L_1 edge jump was found to be 10% of the combined $L_{3,2}$ edge jump and has no pronounced features. The experimental data for the combined edges for the lowest temperature of 70 K are shown in Fig. 1. In order to understand the effect of the overlap of the two edges we compared the experimental EXAFS data to a FEFF7 simulation of the combined edges. For this simulation we calculated $\mu_{L_3}(E)$ and $\mu_{L_2}(E)$ and added the contributions taking edge jump ratios of $J_{L_3}:J_{L_2} = 2:1$ into account. The best agreement between theory and experiment was achieved with a bulk bcc structure for Fe with a Debye temperature of $\theta_D = 520$ K. The good agreement shown in Fig. 1 indicates that the data can be described by simply adding the L_2 contribution to the L_3 contribution. With the help of the ab initio simulation every peak in the Fourier transform of the data [shown in Fig. 1(b)] can be related to specific scattering paths. The main contribution of

FIG. 1. Comparison of the FEFF7 simulation (dotted line) to experimental EXAFS data (solid line) for the combined L_3 and L_2 edges. (a) The k weighted EXAFS oscillations $k \cdot \chi_{L_3+L_2}(k)$ are well reproduced by the simulation in phase as well as in amplitude. (b) The Fourier transform (FT) $[k \cdot \chi_{L_3+L_2}(k)]$.

the Fourier transform contains two single scattering paths (nearest and next nearest neighbor). The contributions in Fourier transform for higher distances ($R > 3.6$ Å) are also described well by the simulation. A more detailed analysis of the scattering paths of the higher shells shows that one finds a complicated interference of single and multiple scattering paths in this range. Therefore the temperature dependence of the main peak only will be investigated here.

We will later analyze the data of the L_3 edge only since the L_3 edge interferes destructively with the L_2 edge for the MEXAFS case. Therefore we separated the contributions of the L_3 and L_2 edges by using an iterative Van Cittert deconvolution method in energy space.¹⁴ To test the performance of this method we deconvoluted the EXAFS simulation of the combined edges and compared the result to the initial simulation of the L_3 edge. Having found perfect agreement we can establish this method as a standard tool for these kinds of investigations. As we have to analyze the temperature dependence of the MEXAFS for the L_3 edge only we will discuss the temperature dependence of the EXAFS for the L_3 edge as well. However, we find the same structural and dynamic results for the EXAFS for the dataset of the combined edges as for the deconvoluted dataset of one edge. The deconvoluted experimental EXAFS data of the L_3 edge are shown in Figs. 2(a) and 2(b). It turns out that the peak positions in the Fourier transform $FT[k \cdot \chi_{L_3}(k)]$ [Fig. 2(b)] of the L_3 edge are the same as those of the combined edges $FT[k \cdot \chi_{L_3+L_2}(k)]$.

As the main peak in the Fourier transform contains the nearest and the next nearest neighbor distance contributions, we had to perform a least square fit using FEFFIT¹⁵ for the analysis of the temperature dependence of the main peak. This code modifies the Debye temperature of the two scattering paths calculated with FEFF7 to get the best fit to the experimental data. As the Fourier transform of the experimental data exhibits a small temperature dependence on the main peak position, indicating the presence of small anharmonicity of the absorber-backscatterer pair potential, a tem-

FIG. 2. The temperature dependent deconvoluted L_3 EXAFS data (a), (b) in comparison to the deconvoluted L_3 MEXAFS (c), (d) data. Although the data have been taken at a longer k range, the data are shown in a smaller k range because the MEXAFS noise level became too high for an appropriate fit above $k > 9.0$ Å⁻¹. Note that the EXAFS Fourier transform (a) is different from that in Fig. 1(b) due to interference effects of the L_3 edge by the L_2 edge. A similar difference is observed in the MEXAFS data (d) compared to the EXAFS data (b) since the magnetic and the spin averaged damping must not be the same. The temperature dependent damping can clearly be seen in the Fourier transform (b), (d). Note the stronger damping for the MEXAFS data.

perature dependent third cumulant $c_3(T)$ calculated from the linear expansion coefficient for Fe was included in the fit.¹ The clear temperature dependence of the experimental EXAFS data was fitted with the correlated Debye model¹⁶ yielding a Debye temperature of $\theta_D = (520 \pm 40)$ K (see Fig. 3) in good agreement with calorimetric measurements for the bulk system [θ_D (calorimetric) = 470 K].¹⁷ The damping of the EXAFS oscillations is described by the mean square relative displacement $\sigma_{\text{tot}}^2(T) = \sigma_{\text{dyn}}^2(T) + \sigma_{\text{stat}}^2$ where $\sigma_{\text{dyn}}^2(T)$ describes the dynamic disorder due to thermal vibrations and σ_{stat}^2 is a measure of the static disorder. As the amplitude of the fit agrees quite well with the experiment, no additional static disorder (σ_{stat}^2) had to be introduced for the spin averaged EXAFS. This shows that the polycrystalline films are well ordered ($\sigma_{\text{stat}}^2 \leq 2 \times 10^{-3}$ Å²) from a local point of view and must therefore consist of large crystallites. The MEXAFS analysis is not as straightforward as that for the EX-

FIG. 3. The temperature dependence of the dynamic part of the MSD $\sigma_{\text{dyn}}^2(T)$ for the nearest neighbor distance (R_1) for the EXAFS data (closed circles) and for the MEXAFS data (open circles). The solid line and the dotted line depict the temperature dependence of the MSD calculated by the Debye model.

AFS. The reason is the different way in which the L_3 edge interferes with the L_2 edge in the helicity dependent investigation. The EXAFS/MEXAFS signal of the combined edges can be explained as

$$\chi_{L_3+L_2}(E) = \frac{2}{3}[\chi_{L_3}(E) + \alpha \cdot \chi_{L_3}(E + \Delta E)], \quad (1)$$

with $\chi_{L_2}(E) = \alpha \cdot \chi_{L_3}(E + \Delta E)$ and $\alpha = \frac{1}{2}$ for EXAFS (quantum degeneracy for L_3 and L_2 edge jumps 2:1) and $\alpha = -1$ for MEXAFS (phase relation for MCXD -1:1). The prefactor $2/3$ takes into account the fact that the edge jump of the combined $L_{3,2}$ edges is 1.5 times larger than the μ_{L_3} edge jump. The negative sign of α for the MEXAFS case leads to destructive interference in the MEXAFS of the combined edges. Due to this interference a deconvolution of the MEXAFS data is necessary. An additional cross check of the deconvolution method is the comparison of the phase shift of the Fourier backtransformed main peak of the Fourier transform for MEXAFS compared to that for EXAFS. We find a phase shift of exactly $\pi/2$ for MEXAFS compared to that for EXAFS as predicted.⁷

The deconvoluted MEXAFS data are shown in Figs. 2(c) and 2(d). A qualitative comparison of the MEXAFS data to EXAFS data shows that the peak positions of the Fourier transforms [Figs. 2(b) and 2(d)] of the main peak are the same for both cases. Also, the temperature dependent damping is comparable. The quantitative FEFFIT yields the same structural results of the Fe bulk bcc structure as we found in the EXAFS analysis. The Debye model analysis of the MEXAFS temperature dependence results in a value for the "magnetic" Debye temperature of $\theta_{D,m} = (400 \pm 40)$ K, showing that the temperature dependence of the MEXAFS data is even stronger than that of the EXAFS. This means that the mean square relative displacement $\sigma^2(T)$ reveals a stronger increase with temperature for the MEXAFS compared to the EXAFS as shown in Fig. 3. This result is surprising at first since the Curie temperature of bulk Fe is $T_C = 1050$ K and therefore a temperature range of 70–400 K results in a reduced temperature range [$t = (T_C - T)/T_C$] of 0.9–0.6. In this temperature range one does not expect a strong temperature dependence of the magnetic signal. Nevertheless one can understand our findings by the scattering of the photoelectron. The MEXAFS signal is determined by the difference in scattering potential for the spin up electron and

the spin down electron. Although the magnetic behavior of the Fe sample is determined by the 3d bands, the difference in scattering potential has the same form as the spin averaged potential.⁷ Therefore any deviation from equilibrium due to thermal vibrations still affects the MEXAFS signal. This explains why the dynamic part of mean square relative displacement $\sigma_{\text{dyn}}^2(T)$ shows about the same increase with higher temperatures that we find for MEXAFS as compared to EXAFS. As magnetic fluctuations are also present in the reduced temperature range of 0.9–0.6, we can understand the even stronger temperature dependence for the spin-dependent MEXAFS compared to the spin averaged EXAFS.

To summarize, we have found that the temperature dependence of the MEXAFS is not only determined by the temperature dependence of the magnetic moment (which is probed in the near edge MCXD technique) but also by atomic thermal vibrations. Since we find an even stronger temperature dependence in the MEXAFS compared to the EXAFS, we find additional local magnetic disorder which maybe can be explained by magnetic fluctuations.

Magnetoresistance in single Fe(001) ultrathin films

S. Yuasa,^{a)} T. Katayama, M. Nývlt, and Y. Suzuki

T. Yori

College of Science and Technology, Nihon University, Funabashi 274-8501, Japan

Magnetoresistance in Au(001)-sandwiched Fe(001) ultrathin films was investigated at $T=1.6$ K. Effects of both the Fe layer and the Au cap layer were investigated using wedge-shaped Fe and Au cap layers. The total thicknesses of the films were kept much thinner than the mean free path of the conduction electrons in order to enhance the magnetoresistance by electron channeling between the surface and the substrate. The Fe wedge-shaped films in the range $d_{\text{Fe}}=0-4$ Å showed a granular-type giant magnetoresistance (GMR) because of a discontinuity in the Fe layer. The films with $d_{\text{Fe}}=4-25$ Å also showed that the GMR component through the Fe layer is continuous. In the Au cap wedge-shaped films, the GMR component nearly vanished at $d_{\text{Au cap}}=0$. The MR ratio increased linearly with $d_{\text{Au cap}}$ in the range $d_{\text{Au cap}}=0-50$ Å and saturated at $d_{\text{Au cap}}\sim 130$ Å. Moreover, the CuO overlayer on the Au cap wedge-shaped film resulted in a 25% decrease in the MR ratio in the whole $d_{\text{Au cap}}$ range. These phenomena can be interpreted as differences in spin flip probability for electron reflections on the surface and at the interfaces. © 1998 American Institute of Physics. [S0021-8979(98)50411-2]

The giant magnetoresistance (GMR) effect in magnetic multilayers is mainly caused by spin-dependent scattering of conduction electrons through ferromagnetic layers with parallel or antiparallel magnetization configurations. In metallic multilayers with two ferromagnetic layers so-called spin-valve films, reflections of conduction electrons at the free surface and at the interface between the buffer layer and the substrate, are considered to have a larger influence on GMR compared to multilayers with many ferromagnetic layers. It has recently been reported that the MR ratio in spin-valve films changes with various kinds of cap layers,¹ showing the importance of electron scattering at the surface and at the interface. This effect has been attributed to the change in specularity of the reflection, but details of it are still unclear.

In order to investigate the effect of surface reflection on magnetoresistance, multilayered films with small numbers of ferromagnetic layers are suitable. For this reason, we focused on a single ferromagnetic ultrathin layer with a buffer layer and a cap layer of nonmagnetic metal. The magnetoresistance in the single ultrathin ferromagnetic layer had been studied in Au/Co/Au system earlier by Kolb *et al.*² They deposited a Co(0001) wedge-shaped ultrathin layer ($d_{\text{Co}}=0-8$ Å) sandwiched between a buffer layer (230 Å) and a cap layer (230 Å) of Au(111) onto a glass substrate, and observed GMR up to 5% at low temperature. The MR ratio reaches a maximum value at $d_{\text{Co}}\sim 3$ Å which corresponds to a crossover from a discontinuous (i.e., granular) to a continuous Co layer. Above $d_{\text{Co}}=6$ Å, where the Co layer is continuous,³ the GMR component still appears because of the small magnetic domain sizes.^{2,3} Even taking into account the granular character and the fine domain structure of the Co layer, the MR ratio is quite large for a single ultrathin ferromagnetic layer with much thicker nonmagnetic buffer and

cap layers. The MR is considered to be enhanced by electron channeling and a high specular reflection at the free surface and/or at the interface between the buffer layer and the substrate. If the total thickness of the film is much smaller than the mean free path of the conduction electrons, the current is mainly dominated by electron channeling. This increases the chances of spin-dependent scattering which occurs when electrons go across the ferromagnetic ultrathin layer. An increase of specular reflection enhances the MR ratio by lowering the resistivity of the film. Besides the specularity of the reflection, spin flip scattering at the surface and at the interface may also influence the magnetoresistance. However, this effect is unclear at the present stage.

In order to investigate the effect of electron reflections at the surface and at the interface between the buffer layer and the substrate, we measured the magnetoresistance in a Au(001)/Fe(001)/Au(001) system in which we had been studying quantum well oscillations of the magneto-optical Kerr effect.^{4,5} We selected this system because layer-by-layer growth and lattice matching are better than those in the Au(111)/Co(0001)/Au(111) system.

FIG. 1. Schematic cross sections of (a) a Fe wedge-shaped film and (b) an Au cap wedge-shaped film.

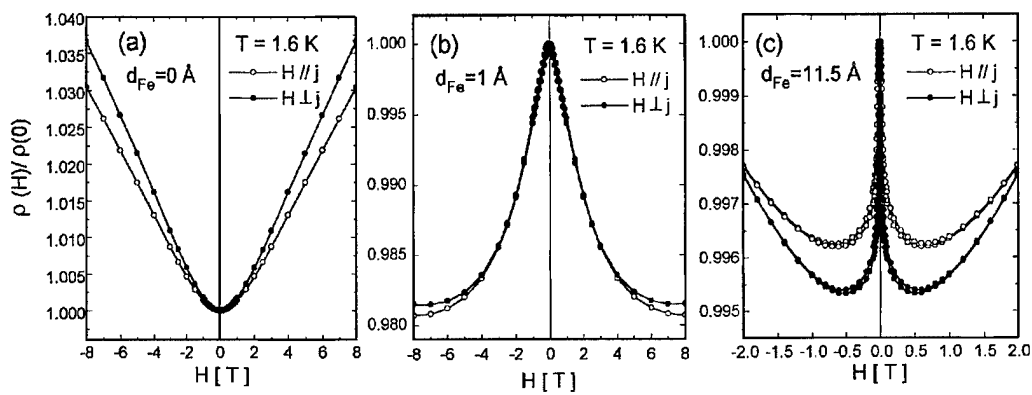

FIG. 2. Typical MR curves in the Fe wedge-shaped samples at 1.6 K for various Fe thicknesses (a) $d_{\text{Fe}}=0$, (b) $d_{\text{Fe}}=1$, (c) $d_{\text{Fe}}=11.5$.

The samples were prepared by the molecular beam epitaxy (MBE) deposition technique under pressure in the 10^{-10} Torr range. Polished MgO(001) single crystals were used as the substrates. The deposition process was observed and controlled by quartz thickness monitors and by reflection high energy diffraction (RHEED). For electric transport measurements, samples with relatively thin buffer layers were prepared as shown in Fig. 1. After thermal flashing the substrate at 850 °C for 10 min, a Ag buffer layer of 200 Å and a Au buffer layer of 40 Å were both deposited at room temperature. To prevent mixing of the Au and Fe, an ultra-thin Fe layer and a Au cap layer were deposited at room temperature. After deposition of the Au(001) buffer and cap layers, a 1×5 RHEED, reconstruction pattern was clearly observed. Wedge-shaped layers were prepared by continuously moving a shutter over the sample during the deposition.

The samples were either Fe wedge shaped [Fig. 1(a)] or Au cap wedge shaped [Fig. 1(b)]. Two Fe wedge-shaped samples were prepared, one with Fe thickness d_{Fe} varying from 0 to 18 Å and the other with d_{Fe} from 0 to 200 Å. For the Au cap wedge, two samples were prepared with d_{Au} ranging from 10 to 50 Å, and from 10 to 250 Å. The minimum thickness of the Au cap layer was set at 10 Å, because below this thickness the Fe layer is oxidized in air.

Quantum well oscillations of the polar Kerr effect were measured as a function of Fe and Au cap layer thickness at room temperature in order to check the quality of the samples by comparing them with those with thicker buffer layers that were studied previously by Kerr effect measurements.^{4,5} The surface morphology and the magnetic domain structure were observed by atomic force microscopy (AFM) and by magnetic force microscopy (MFM), respectively. The electric resistivity was measured by a dc four-probe method at 1.6 K in a magnetic field up to 9 T.

The AFM observation showed that the Au(001) surface in all the samples has a gentle wavy structure with an average period of 1000 Å and an average amplitude of 10 Å. No change of the surface morphology was observed by varying the thicknesses of the Fe and Au cap layers. Clear quantum well oscillations of polar Kerr ellipticity were observed in the Fe wedges with $d_{\text{Fe}} > 4$ Å, indicating good quality of the Fe layer. Ferromagnetic hysteresis curves were also observed for $d_{\text{Fe}} > 4$ Å by a longitudinal Kerr measurement. On the

other hand, no Kerr ellipticity signal was detected for $d_{\text{Fe}} < 4$ Å. This indicates that the Fe layer with $d_{\text{Fe}} < 4$ Å is discontinuous and superparamagnetic at room temperature. The Au cap wedge-shaped films also showed quantum well oscillation of the polar Kerr effect, indicating that there is no oxidation of the Fe layer when $d_{\text{Au cap}} \geq 10$ Å.

Figures 2 and 3 show typical MR curves for various Fe thicknesses in the Fe wedge-shaped films and a MR ratio, $\Delta\rho(H)/\rho(H=0)$, as a function of Fe thickness, respectively. The magnetoresistance of the Fe wedge can be classified into four parts depending on the Fe thickness as follows.

- (1) $d_{\text{Fe}}=0$ [Fig. 2(a)]: The film with no Fe layer simply shows the magnetoresistance of Ag and Au, which arises from the Lorentz force acting on conduction electrons.⁶
- (2) $d_{\text{Fe}}=0.3\text{--}4$ Å [Fig. 2(b)]: The film shows typical granular-type GMR because of the discontinuity of the Fe layer. The MR ratio reaches a maximum in this range as seen in Fig. 3(a).
- (3) $d_{\text{Fe}}=4\text{--}30$ Å [Fig. 2(c)]: The film shows a finite GMR component although the Fe layer is continuous in this range. The difference in the MR ratio in the two field directions ($H \parallel j$ and $H \perp j$) is due to anisotropic MR (AMR) in the Fe layer. The GMR in this range is considered to originate from a fine domain structure although the magnetic domains were not observed by MFM maybe because of too small a stray field. In this

FIG. 3. MR ratio $[\rho(0) - \rho(H)]/\rho(0)$ in the Fe wedge-shaped samples at 1.6 K as a function of Fe thickness, d_{Fe} .

FIG. 4. MR, ratio $[\rho(0) - \rho(H)]/\rho(0)$ in the Au cap wedge-shaped samples at 1.6 K as a function of Au cap thickness, $d_{\text{Au cap}}$.

range, the MR ratio gradually decreases with d_{Fe} (see Fig. 3), which can be attributed to an increase of magnetic domain size, as is also observed in Co(0001) ultrathin films.³

- (4) $d_{\text{Fe}} > 30 \text{ Å}$: The film shows only AMR, with no GMR component. In this range, magnetic domains with average sizes larger than $10 \mu\text{m}$ were observed by MFM. The disappearance of the GMR is consistent with the macroscopic domain size in which there is very little chance for conduction electrons to go from one domain to neighboring domains.

Figure 4 shows the MR ratio $[\rho(0) - \rho(H)]/\rho(0)$ in the Au cap wedge-shaped samples as a function of Au cap thickness, $d_{\text{Au cap}}$. When extrapolating $d_{\text{Au cap}}$ to 0, the GMR component almost vanishes. The MR ratio increases approximately in proportion to $d_{\text{Au cap}}$ when $d_{\text{Au cap}} < 50 \text{ Å}$, and saturates at $d_{\text{Au cap}} \sim 130 \text{ Å}$ above which it slightly decreases with $d_{\text{Au cap}}$. This behavior can be understood as follows. The mean free path of conduction electrons in the Ag and Au layers was roughly estimated to be about $3\text{--}5 \mu\text{m}$ at 1.6 K using the same method as in Ref. 7. Since the total thickness of the film ($260\text{--}500 \text{ Å}$) is much smaller than the mean free path, the current flows mainly by electron channeling (Fig. 5). In the film with no Au cap layer [Fig. 5(a)], conduction electrons with a spin antiparallel to the magnetization of a domain in the Fe layer are reflected on an interface between the Fe and the buffer layers because of spin-dependent scattering, while the electrons with a spin parallel to the magnetization go into the Fe layer and are reflected on the surface.

FIG. 5. Schematic illustrations for the paths of conduction electrons in the films (a) without a Au cap layer and (b) with a Au cap layer.

Because the Fe layer is ultrathin, the spin-dependent scattering on the interface barely changes the mean free path of electrons. Therefore, GMR does not appear when there is no cap layer. On the other hand, in the film with Au cap layer, spin-dependent scattering in the Fe layer changes the mean free path of conduction electrons [Fig. 5(b)]. Thus, GMR appears with an increase of the cap layer thickness. The saturation of MR ratio at $d_{\text{Au cap}} \sim 130 \text{ Å}$ can be interpreted as a shunting effect in the cap layer.

Moreover, we have studied the effect of an oxide overlayer on the Au cap wedge-shaped sample. A 30-Å -thick Cu layer was deposited on the Au cap wedge and oxidized in air for one day. The CuO capping increased the film resistivity by 6%. This can be understood by a lower specular reflectivity at the interface between Au and CuO than that at the free surface of Au. On the other hand, MR ratio decreased by 25% as a result of CuO capping (Fig. 4). The large decrease of MR ratio cannot be explained only by the change of a specular reflectivity. This indicates that probability of spin flip scattering during surface reflection is increased by the CuO capping.

As the size of the giant magneto resistive (GMR) devices continues to decrease into submicrometer regime, the demagnetizing field from the magnetic layers will increase to very high values, prohibiting switching with a reasonably small current. The most feasible way to reduce it is to make the magnetic layers thinner. Single layers of NiFeCo and CoFe films as well as multilayers consisting of these with various underlayers have been deposited by rf diode sputtering in a magnetic field. NiFeCo becomes nonmagnetic at 15, 10, and 6 Å when using Ta, Si₃N₄, and Cu underlayers, respectively. The magnetization of NiFeCo films sandwiched with Cu decreases as the films become thinner, indicating that about one atomic layer loses its magnetic moment at each interface with Cu. The induced magnetic anisotropy is a strong function of the NiFeCo film thickness, changing from 7 Oe for 20 Å to 17 Oe for 100 Å. CoFe films lose very little magnetic moment at the interfaces with Cu. Multilayers of [NiFeCo/Cu/CoFe/Cu] with different Cu underlayer thickness have been made and the magnetic and GMR properties show a strong dependence on the Cu buffer layer thickness due to different interface roughnesses. With proper designing of the interfaces, these very thin magnetic films have high potential for ultrahigh-density magnetic memory and other applications. © 1998 American Institute of Physics.

[S0021-8979(98)37711-7]

For future ultrahigh-density giant magneto resistive (GMR) magnetic random access memory (MRAM) and other applications, the size of the devices will continue to decrease to submicrometer and beyond. Accordingly, the demagnetizing field will increase as the size gets smaller,¹ leading to a prohibitively high switching field which needs to be surpassed by a current in the device. In order to reduce this demagnetizing field the most feasible way is to use very thin magnetic layers. Though other means such as molecular beam epitaxy (MBE) are capable of making very thin magnetic layers,² sputtering remains the most practical technique for manufacturing. The objectives of this study are to identify how thin a magnetic layer can be made with sputtering, to find out if they are compatible with other materials which have to be in contact with them, and to determine their magnetic properties. NiFeCo and CoFe films are chosen because of their excellent magnetic properties in bulk form and extensive usage in practical film applications.³

Films were deposited by rf diode sputtering in a PE2400 system equipped with four 8 in. targets, a single wafer load lock, and a water cooling wafer chuck.⁴ The deposition parameters are 175 W power, 750 V target bias voltage, 20 mTorr ultrapure Ar, and a target-substrate spacing of 1.5 in. The substrates are 4 in. Si(100) wafers coated with 2000 Å of Si₃N₄ by low pressure chemical vapor deposition (LPCVD). The base pressure was better than 1.5×10^{-7} Torr before deposition. A magnetic field of 1.6 kA/m (20 Oe) was applied during magnetic layer deposition to induce an easy magnetic axis. The entire deposition process was computer controlled.

Magnetic properties were measured using a vibrating

sample magnetometer (VSM) and an alternating gradient force magnetometer (AGM). Magneto-transport properties were measured using a computer controlled four-point probe.

NiFeCo films of varying thickness are deposited on different buffer layers of Ta, Si₃N₄, and Cu. NiFeCo films become nonmagnetic at a thickness of 15, 10, and 6 Å on Ta, Si₃N₄, and Cu buffer layers, and with Ta, Ta, and Cu over coatings, respectively. Among these three buffer layers, Cu is the best in retaining the magnetization of NiFeCo. On Cu buffer layers the NiFeCo magnetization decreases as the film becomes thinner, as shown in Fig. 1. It is estimated that there is a magnetically dead layer of about 2 Å at each interface of NiFeCo with Cu, except at 6 Å nominal thickness where the magnetization becomes zero. The magnetization of 100 Å NiFeCo is about 1100 emu/cc, similar to the bulk value at this stoichiometry.⁵ Figure 1(b) shows the thickness dependence of the induced anisotropy field H_k . H_k is about 17 Oe at 100 Å, decreases when the film is thinner, is about 7 Oe at 20 Å, and becomes negligibly small when the film is much thinner than 20 Å. When the Co concentration in NiFeCo is increased from 20 at. % to 40 at. %, H_k increases to 23 Oe for a 100 Å film and 11 Oe for a 20 Å film, as shown in Fig. 1(b).

Figure 2 shows the CoFe thickness dependence of the magnetization with Cu buffer and over coats. These CoFe films have little moment loss (~ 0.5 Å at each interface) with a magnetization of about 1450 emu/cc, similar to its bulk value at this stoichiometry.⁵ The difference in their magnetization reductions for CoFe and NiFeCo is likely due to the fact that Ni is metallurgically miscible with Cu, and Co and Fe are not.

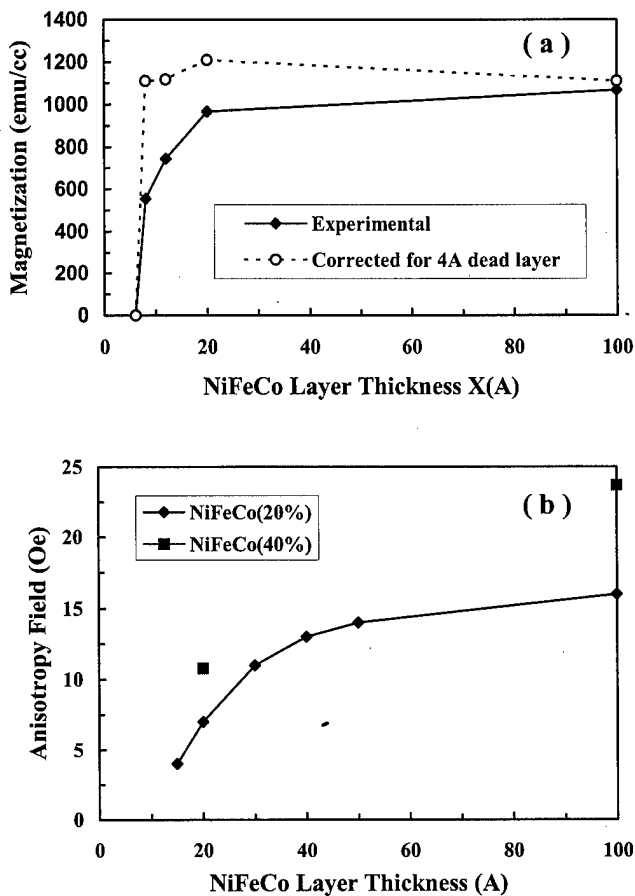

FIG. 1. Thickness dependence of magnetization (a) and anisotropy field H_K (b) for NiFeCo single layers of varying thickness sandwiched between Cu buffers and over coats.

Figure 3 shows the hysteresis loops of a 100 Å NiFeCo film with (a) and without (b) a Cu buffer layer of 1500 Å. A thick Cu underlayer will be necessary in vertical GMR MRAM as the bottom conductor. The thick Cu underlayer increases the coercivity of the NiFeCo layer dramatically, to

FIG. 2. Thickness dependence of the magnetization of CoFe single layers sandwiched between a Cu underlayer and over coat.

FIG. 3. Hysteresis loops of 100 Å NiFeCo films with (a) and without (b) a 1500 Å buffer layer, with applied field parallel and perpendicular to the induced easy axes. Notice the difference in field scales.

37 Oe at 1500 Å Cu from 2 Oe with no Cu. This coercivity value is about twice as much as the intrinsic induced anisotropy field.

In order to search for the origin of the high coercivity with thick Cu underlayers, atomic force microscopy (AFM) images were taken with tapping mode on Si_3N_4 and Cu 1500 Å, as shown in Fig. 4. Cu 1500 Å has much larger grains and rougher surface than Si_3N_4 . The rms roughnesses are 15 and 2 Å for Cu 1500 Å and Si_3N_4 , respectively. It is clear that the rougher surface of the Cu causes the increase in coercivity of NiFeCo. Similarly, a CoFe single layer has a coercivity of 13 Oe with a 40 Å Cu buffer layer and 50 Oe with a 1500 Å Cu buffer layer.

Figure 5 shows the hysteresis loops of dual bilayers of $-\text{XCu}[\text{12NiFeCo}/\text{75Cu}/\text{11CoFe}/\text{75Cu}]_2$ with a varying Cu buffer layer thickness X . The switching fields for both the soft NiFeCo layers and the hard CoFe layers increase as the Cu buffer layer becomes thicker, because the interface becomes rougher. The thick Cu spacer of 75 Å is required to totally eliminate the exchange coupling between the magnetic layers. The antiparallel state is only realized due to the difference in the coercivities of the NiFeCo and CoFe layers.

Figure 6 gives current-in-plane (CIP) GMR plots for the dual bilayers with a 40 Å Cu buffer layer (a) and a 1500 Å buffer layer (b). Due to the thick Cu spacers as well as the

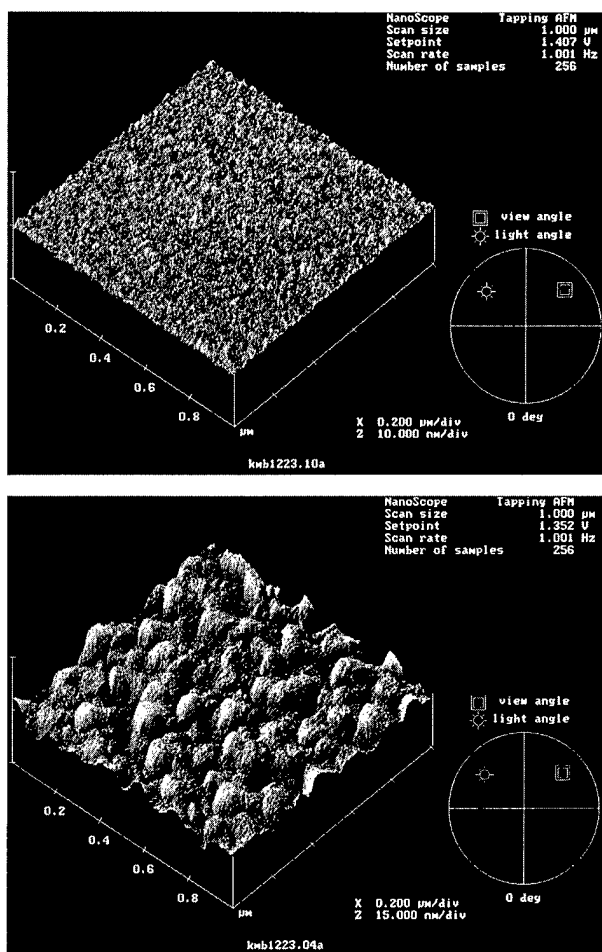

FIG. 4. AFM surface images of Si(100)/Si₃N₄ 2000 Å (a) and Si(100)/Si₃N₄ 2000 Å/Cu 1500 Å (b) using tapping mode. The rms roughnesses are 15.0 and 2.0 Å, respectively, with and without Cu. The vertical scale z is 10 nm for (a) and 15 nm for (b).

FIG. 5. Hysteresis loops of dual bilayers of $-XCu-[12NiFeCo/75Cu/11CoFe/75Cu]_2$ with varying Cu buffer layer thickness X . All numbers are in angstroms.

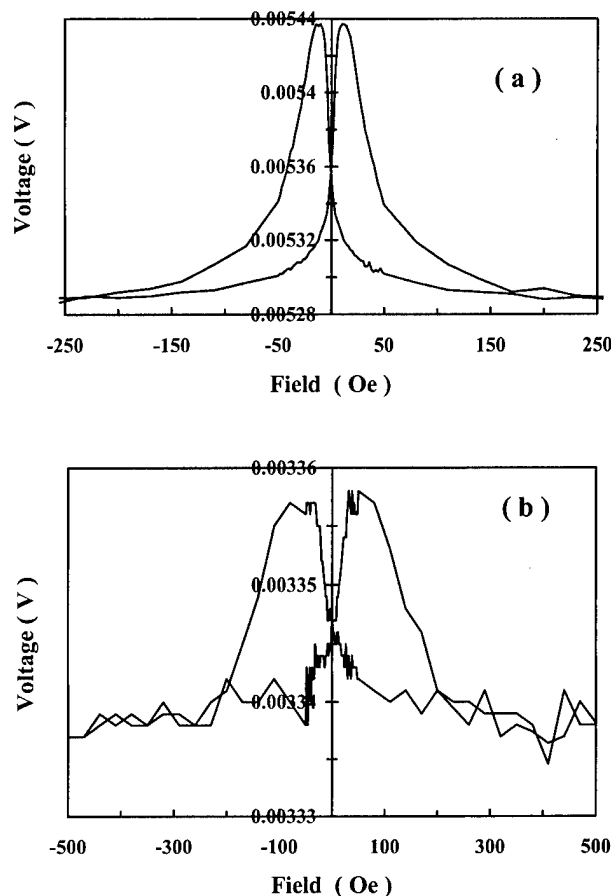

FIG. 6. Magneto resistive traces of $-[12NiFeCo/75Cu/11CoFe/75Cu] \times 2$ with 40 Å Cu (a) and 1500 Å Cu (b) buffer layer. Notice the difference in field scales.

thick Cu buffer layer the CIP GMR is only a few percent to a fraction of a percent. Current perpendicular to plane (CPP) GMR on patterned devices is about 16%, with a high switching field around 200 Oe mainly from the rough surface.⁶ In order to make the device work at a reasonably low switching field, the starting surface has to be made smoother through either improved sputtering or a polishing technique such as chemical-mechanical polishing (CMP).

Ferromagnetic resonance linewidth in thin films coupled to NiO

R. D. McMichael,^{a)} M. D. Stiles, P. J. Chen, and W. F. Egelhoff, Jr.
National Institute of Standards and Technology, Gaithersburg, Maryland 20899

The out-of-plane angular dependence of the ferromagnetic resonance linewidth, ΔH , has been measured for thin magnetic films coupled to NiO and for uncoupled control films. In the control films, ΔH is described by nearly angle-independent damping parameters. In the NiO-coupled films, however, the damping was found to depend strongly on magnetization orientation, with linewidth values comparable to the control samples at normal orientation, but several times larger when the magnetization lies in plane. The additional linewidth in the NiO-coupled films follows the angular dependence of the number of nearly degenerate spin wave modes, in agreement with the predictions of a two-magnon scattering model of damping which incorporates a spin wave dispersion relation suitable for ultrathin films. © 1998 American Institute of Physics. [S0021-8979(98)37811-1]

I. INTRODUCTION

Increased ferromagnetic resonance linewidth^{1,2} is a part of the complex phenomenology of exchange anisotropy that includes shifted hysteresis loops,³ rotational hysteresis,⁴ shifts in the Brillouin scattering frequency,⁵ and ferromagnetic resonance (FMR) field.^{1,2,6} Explanations of the increased linewidth in ferromagnet/antiferromagnet bilayers have been based on a dispersion of resonance fields due to dispersion of the exchange bias.^{1,2} This article presents, for the first time, measurements of the FMR linewidth, ΔH , as a function of the magnetization orientation from in-plane to film normal. These results are compared with the predictions of a two-magnon model of FMR damping.

II. EXPERIMENT

The samples in this study were deposited by dc magnetron sputtering in 0.25 Pa (2 mTorr) Ar. The base pressure before depositing a film was approximately 10^{-6} Pa (10^{-8} Torr) of which 90% was hydrogen. The films consisted of Ni₈₀Fe₂₀, Co, and Co₃₀Ni₃₅Fe₃₅ deposited on 50 nm NiO and capped with Au or Ta, and the magnetic film thickness ranged from 4.0 to 10.0 nm. These films were deposited in a field which set the direction of the exchange anisotropy field, \mathbf{H}_{ex} . The corresponding control films were deposited with 2.0 nm layers of Ta separating the magnetic films from the NiO.

Ferromagnetic resonance spectra were taken using an x-band spectrometer operating at 9.78 GHz. The samples were mounted on the side of a quartz rod passing through the center of the TE₁₀₂ microwave cavity, and sample orientation was controlled by a goniometer with a precision of $\pm 0.12^\circ$. Samples were mounted with \mathbf{H}_{ex} directed parallel to the rotation axis, along the z direction (see Fig. 1) so that the applied field, \mathbf{H} was always perpendicular to \mathbf{H}_{ex} . Resonance fields and peak-to-peak field linewidths of 10 nm thick Ni₈₀Fe₂₀ films on NiO and on Ta are shown in Fig. 2.

The free energy, \mathcal{F} , of the magnetization is modeled by

$$\mathcal{F} = K_u \sin^2 \theta \sin^2 \phi + K_a \sin^2 \theta \cos^2 \phi - \mu_0 \mathbf{M} \cdot \mathbf{H} - \mu_0 \mathbf{M} \cdot \mathbf{H}_{\text{ex}} - \mu_0 \mathbf{M} \cdot \mathbf{H}_{\text{ra}}, \quad (1)$$

where K_u and K_a are uniaxial anisotropies with hard axes directed along the y and x directions, respectively. \mathbf{H} is the applied field and \mathbf{H}_{ra} is a rotatable anisotropy field, $\mathbf{H}_{\text{ra}} \parallel \mathbf{M}$, included to model an isotropic negative resonance field shift.⁶ The angles are defined in Fig. 1. The resonance condition is given by

$$(\omega/\gamma)^2 = (M^2 \sin^2 \theta)^{-1} [\mathcal{F}_{\theta\theta} \mathcal{F}_{\phi\phi} - \mathcal{F}_{\theta\phi}^2], \quad (2)$$

where the subscripts indicate partial derivatives, evaluated at values of θ and ϕ which minimize \mathcal{F} , and $\gamma = g\mu_B/\hbar \approx 1.76 \times 10^{11} \text{ T}^{-1} \text{ s}^{-1}$.

The H_{res} data was fit using an orthogonal least-squares algorithm⁷ to obtain values for the parameters in Eq. (1). The fit parameters are then used to calculate ϕ and values of $d\omega/dH$ corresponding to each data point.

While the measurements were made by sweeping H at fixed ω , theoretical linewidth calculations are simpler at fixed H . To make comparisons with theoretical results, values for $\Delta\omega$ are obtained from the ΔH data using $\Delta\omega = (d\omega/dH)\Delta H$ where $d\omega/dH$ is calculated numerically using parameters obtained from the H_{res} fit described above. Plots of $\Delta\omega/\gamma$ vs ϕ for the 10 nm thick Ni₈₀Fe₂₀ samples are shown in Fig. 3. There is a smooth increase in $\Delta\omega$ in the NiO coupled film as \mathbf{M} is rotated from the sample normal (90°) to in-plane (0°). In contrast, $\Delta\omega$ does not depend strongly on ϕ for the Ni₈₀Fe₂₀ film on Ta. Other films with different thick-

FIG. 1. Coordinate system used in to describe the orientation of \mathbf{M} , \mathbf{H} , and \mathbf{k} with respect to the film.

nesses and compositions described above were measured, and the results show very similar linewidth behavior.

III. TWO-MAGNON THEORY

The ferromagnetic film is modeled as a $N_x \times N_y \times N_z$ rectangular array of spins with lattice parameter a . The thickness of the film, d , is given by $d = N_y a$. The coordinate system used to describe the orientation of \mathbf{M} , \mathbf{H} , and the spin wave propagation vector, \mathbf{k} , is shown in Fig. 1.

In a uniform film, the normal modes can be described as a uniform precession mode, which couples to the microwave excitation field, and a manifold of spin wave modes which are not directly excited. Nonuniformities will induce coupling between the normal modes, leading to a broadening of the resonance.

The two-magnon model of FMR damping⁸⁻¹⁰ treats nonuniformities as perturbations. The scattering rate, $\lambda_{0,k \rightarrow \lambda}$, of uniform precession, or $k=0$, magnons into other, $k \neq 0$ spin wave mode is

$$\lambda_{0,k \rightarrow \lambda} = \frac{2\pi}{\hbar} \sum_k |A_k|^2 \delta(\hbar\omega_0 - \hbar\omega_k), \quad (3)$$

where A_k is the coefficient of the perturbation Hamiltonian term which couples the uniform precession and spin wave modes. As λ represents the rate of decay of a population of

$k=0$ magnons, it also represents a contribution to the frequency linewidth, $\Delta\omega = \lambda + \delta\omega_0$, of continuously driven uniform precession.

If the inhomogeneity is restricted to the interface, the perturbation Hamiltonian can be modeled as an exchange bias or anisotropy field, $H_p(\mathbf{r})$, acting on the first layer of atoms in the ferromagnet. This field varies randomly from grain to grain along the interface, but is correlated over a distance, ξ , corresponding to a grain size. When the expectation value of $|A_k|^2$ is calculated using $A_k = \gamma\hbar\mu_0/\sqrt{N}H_p(\mathbf{k})^9$ under the assumption that $\langle H_p(\mathbf{r})H_p(\mathbf{r}') \rangle \approx \langle H_p^2 \rangle \exp[-|\mathbf{r}-\mathbf{r}'|/\xi]$,

$$\lambda = \frac{2\pi\gamma^2\mu_0^2\langle H_p^2 \rangle}{N_x N_z d^2} \sum_k \frac{2\pi\xi^2}{[1-(k\xi)^2]^{3/2}} \frac{\delta\omega_k/\pi}{[\delta\omega_k^2 + (\omega_0 - \omega_k)^2]}. \quad (4)$$

In this expression, the δ function in Eq. (3) has been replaced by a Lorentzian with $\delta\omega_k$ chosen to represent the intrinsic spin wave linewidth.

The spin wave dispersion relation, $\omega_k = \omega(k, \psi_k, H, \phi_h, M, \phi, d)$, is the source of angular dependence in Eq. (4). It is derived assuming uniform precession through the thickness of the film because in the thickness range of interest, spin waves with components of \mathbf{k} perpendicular to the plane of the film will have $\omega_k > \omega_0$ and will not count in the sum. Starting with $d\mathbf{M}/dt = -|\gamma|\mathbf{M} \times \mathbf{H}$ and using magnetostatic fields given by

$$H_y^D(\mathbf{k}) = -NkM_y(\mathbf{k}), \quad (5)$$

$$H_{x,z}^D(\mathbf{k}) = -\mathbf{k}[M_x(\mathbf{k})k_x + M_z(\mathbf{k})k_z](1 - N_k)/|k|^2, \quad (6)$$

where $N_k = [1 - \exp(-kd)]/kd$,¹¹ the resulting dispersion relation is

$$\begin{aligned} (\omega_k/\mu_0\gamma)^2 = & [H_i + Dk^2 + M(1 - N_k)\sin^2 \psi_k] \\ & \times [H_i + Dk^2 + MN_k \cos^2 \phi \\ & + M(1 - N_k)\sin^2 \phi \cos^2 \psi_k] \\ & - [M(1 - N_k)\cos \psi_k \sin \psi_k \sin \phi]^2, \end{aligned} \quad (7)$$

FIG. 5. Thickness dependence of the number of degenerate spin waves calculated for a $\text{Ni}_{80}\text{Fe}_{20}$ film at 34 GHz, using $\mu_0 \delta \omega_k / \gamma = 10$ mT and $\xi = 40$ nm.

where H_i is the internal static magnetic field, D is the spin wave dispersion constant, and the angles are defined in Fig. 1. Spin wave manifolds calculated from Eq. (7) are shown in Fig. 4.

The solid line in Fig. 3 is the result of the two-magnon theory for a 10 nm film of $\text{Ni}_{80}\text{Fe}_{20}$ assuming that $\xi = 40$ nm, which is a typical grain size for these films. To match the experimental data at 0° and 90° , the value of $\mu_0 H_p a / d$ was adjusted to 35 mT and an intrinsic linewidth $\delta \omega_0 = \delta \omega_k = 5$ mT was used.

It is helpful to think about the result in Eq. (4) in terms of two parts: the terms outside the summation having to do with the strength of the scattering of spin waves, and the summation over magnon wavevectors which is essentially a weighted count of the number of spin wave modes having wave vectors matching the spatial fluctuations of the perturbing field and with frequencies close enough to ω_0 to accept the scattered energy. The angular dependence of $\Delta \omega$ is contained entirely within the mode counting terms through ω_k , and the thickness dependence is shared by the mode counting and the scattering strength terms.

The quantity $\Delta \omega d^2 / (H_p^2 a^2)$ contains only the thickness dependence of the mode counting, with the explicit $1/d^2$ thickness dependence of the scattering strength factored out. This quantity is plotted in Fig. 5 as a function of inverse film thickness for $\text{Ni}_{80}\text{Fe}_{20}$ films with \mathbf{M} in plane ($\phi = 0$).

The thickness dependence of the two-magnon model, with an explicit $1/d^2$ dependence in the scattering strength and a $1/d$ thickness dependence in the mode counting does

not agree well with published results^{1,2} which show the linewidth increasing linearly with $1/d$ for $d > 10$ nm and decreasing for a thinner sample. The $1/d^2$ dependence of the scattering strength can be eliminated if the perturbing field is assumed to act on spins throughout the thickness of the sample, rather than on the surface spins. It is interesting to note that the thickness dependence of the mode counting part alone, without the implicit thickness dependence of the scattering strength, is very similar to that of previously published results (see Ref. 2, Fig. 5).

IV. CONCLUSIONS

The experimental results show consistently that for magnetic films deposited on NiO, the FMR linewidth is several times larger for \mathbf{M} in plane than for \mathbf{M} normal to the film, and that the frequency linewidth changes smoothly as a function of magnetization orientation. In agreement with the two-magnon model, these results are consistent with a proportionality between the frequency linewidth and the number of nearly degenerate spin wave modes.

If the perturbation is restricted to the interface, the two-magnon model predicts an explicit $1/d^2$ dependence multiplying the $\sim 1/d$ dependence of the mode counting. This result is not supported by previous experimental data.^{1,2} However, if the perturbation is allowed to act throughout the thickness of the film, there is no explicit thickness dependence and the agreement with experiment is quite good.

Magnetic ordering in Co films on stepped Cu(100) surfaces

S. T. Coyle and M. R. Scheinfein

Dept. of Physics and Astronomy, PSF 470 Box 871504, Arizona State University, Tempe, Arizona 85287

Ultrathin films of Co were grown on Cu(100) and characterized by nanometer resolution secondary electron microscopy, Auger electron spectroscopy, and the surface magneto-optic Kerr effect. An unexpected out-of-plane remanence was detected in many films. The anisotropy of atoms near defects along the Co/vacuum interface calculated via the Néel model indicates that atoms at the bottom corner of a step edge are canted out-of-plane. Full three-dimensional micromagnetics simulations which incorporate site specific anisotropy (including step edges, kinks, and voids) have been performed. Simulations with unidirectional arrays of $[1\bar{1}0]$ steps, such as vicinal surfaces, do not exhibit out-of-plane remanence. Simulations with facets consisting of connected $[110]$ and $[1\bar{1}0]$ steps exhibit out-of-plane remanence of 0.03. This is lower than the experimental value of 0.11. © 1998 American Institute of Physics. [S0021-8979(98)37911-6]

I. INTRODUCTION

Magnetic surface anisotropies play a key role in determining the magnetic properties of thin films and multilayers.¹ Recently the anisotropy of steps has been found to be important in understanding the magnetic behavior of some systems.²⁻⁴ Since the roughness of the Co/Cu interface plays a key role in determining GMR properties,⁵ characterizing the Co/Cu interface including the effect of defects is important. Ultrathin films of Co were grown on Cu(100) in order to study the morphology and the resulting magnetic properties at early stages of growth. The films were characterized by nanometer resolution secondary electron microscopy, Auger electron spectroscopy, and the surface magneto-optic Kerr effect (SMOKE).⁶ An unexpected out-of-plane remanence was detected in many films.

The cause of this out-of-plane component of the magnetization could be related to film morphology at the early stages of growth. One possible mechanism which may produce out-of-plane magnetization is defect related anisotropy on imperfect surfaces. The anisotropy of atoms near defects along the Co/vacuum interface has been calculated. Atoms along the bottom corner of a $\langle 110 \rangle$ step which have strong uniaxial anisotropy canted out-of-plane, may couple to the spins of nearby atoms. A significant out-of-plane component to the magnetization may occur for some critical density of these sites. This short article will address the feasibility of this mechanism for the origin of the perpendicular component to the observed magnetization.

Co grown on substrates with high defect densities resulted in dramatic faceting of step edges and the creation of rectangular pits.⁶ The anisotropy of atoms of low coordination created by this morphology may significantly affect the magnetization of the film, and may thus affect the GMR properties of multilayers. To evaluate the equilibrium magnetic microstructure in such films, and to determine if the anisotropy at sites with low symmetry may be responsible for the observed out-of-plane remanence, full three-dimensional micromagnetics simulations were performed incorporating the calculated site specific anisotropies.

II. EXPERIMENTAL RESULTS

Morphological characterization with concurrent magnetization measurements was obtained from Co grown on bulk single crystal Cu(100) samples.⁶ Cu substrates were cleaned by repeated Ar^+ ion sputter and anneal (600 C) cycles. Co was grown by electron-beam evaporation at rates between 0.05 ML/min and 0.2 ML/min at pressures $< 5 \times 10^{-10}$ mbar (1 ML = 1.53×10^{15} atoms/cm²). Samples were transferred *in situ* into the SMOKE chamber for magnetic characterization, then transferred *in situ* into an ultrahigh vacuum scanning transmission electron microscope for nanometer resolution secondary electron (SE) imaging.⁷ SE micrographs revealed complex growth morphologies which varied between different films. Many films contained high densities of steps, kinks, and facets.

Co/Cu(100) films in this study became ferromagnetic at room temperature at about 1.7 ML. Zero field susceptibility in the paramagnetic regime and remanence in the ferromagnetic regime generally increased with coverage. In many films a second magnetic phase was detected with out-of-plane remanence and a coercivity 5–10 times the in-plane value which increased with Co coverage. Figure 1 contains such Kerr hysteresis loops taken in the longitudinal [Fig. 1(a)] and polar [Fig. 1(b)] geometries⁷ from a 2 ML thick film. As a result of the 45° incident scattering angle, polar signals were five times stronger than the longitudinal signals.⁸ The out-of-plane component of the magnetization in the film in Fig. 1 is therefore ~ 0.11 .

FIG. 1. Kerr hysteresis loops from a sample exhibiting out-of-plane remanence. Part (a) was taken in the longitudinal geometry and (b) was taken in the polar geometry. The Kerr signal is given in arbitrary units, and the scales in (a) and (b) are the same.

III. MICROMAGNETICS SIMULATIONS

The anisotropy of face centered cubic atoms has been calculated for reduced symmetry structures such as steps and kinks following the Néel model of anisotropy,⁹ and including the effects of strain.¹⁰ In agreement with Chuang *et al.*,¹¹ the anisotropy of atoms along the bottom corner of a step edge (step corner) was found to be uniaxial and canted out-of-plane, while the anisotropy of atoms along the top corner of a step (step edge) was uniaxial in-plane along the step direction. The anisotropy of bulk atoms and surface atoms was biaxial in-plane along $\langle 110 \rangle$. The anisotropy of kink edge atoms was biaxial in-plane along $\langle 110 \rangle$ and that of kink corner atoms was uniaxial in-plane along the kink direction. A summary of these results is given in Table I, and a schematic of a Co surface identifying individual sites is presented in Fig. 2. Strain due to the misfit of face-centered-cubic (fcc) Co and fcc Cu has been included in all anisotropy calculations except when noted.

The anisotropy terms (Table I) proportional to $\cos^2 \theta$ extract a high penalty for magnetization out of the plane. Of the remaining terms, those proportional to $L(r_0)$ are larger by a factor of 10^2 than terms containing e_0 or $Q(r)$. The step corner, kink-in corner and kink-out corner sites hold promise for out-of-plane magnetization due to the term proportional to $\sin \theta \cos \theta$. The step corner has an energy minimum which is out-of-plane, while the kink-in corner and kink-out corner sites have energy minima which are in-plane.

These atomic, site specific anisotropy energies have been incorporated into micromagnetics simulations¹² of Co on stepped Cu(100). The simulation searches for solutions to the Landau-Lifshitz-Gilbert equation. The following energies were included: exchange energy, site-specific anisotropy energy, magnetostatic self-energy, and external magnetostatic field energy. The saturation magnetization, exchange stiffness, gyromagnetic frequency gamma, and damping con-

FIG. 2. Schematic representation of atomic sites in the vicinity of a kinked $\langle 110 \rangle$ step. The anisotropy of these sites is given in Table I.

stant alpha were set to the bulk values for Co. This is a continuum model which has been discretized at atomic length scales.

The micromagnetic structure of two monolayer (ML) films has been simulated where the top layer consists of a terrace one half the width of the bottom layer. The two step edges in the top layer were aligned along $[1\bar{1}0]$ or $[100]$. In some simulations kinks were inserted into the step edges at regular intervals and the terrace widths were varied. The simulations used periodic boundary conditions in both in-plane directions. The system was discretized into cells with sides of length $a_0/\sqrt{2}$ on a simple cubic lattice, where a_0 is 0.361 nm. This insured that the volume of the region with

TABLE I. Anisotropy energies for fcc (100) sites described in the text and shown schematically in Fig. 2. Derivations of anisotropy energy and the value of the constants have been given in Ref. 9. Note r , θ , and ϕ have been defined in the usual way. The step direction is $[1\bar{1}0]$. For $[110]$ steps, change ϕ to $\tau - \phi$.

step anisotropy matched the volume occupied by a step oriented along $\langle 110 \rangle$. The system was allowed to relax with no applied field in order to determine the equilibrium magnetization distribution in the film.

No significant out-of-plane ($\langle M_z \rangle > 0.01$) component of the magnetization was present in the equilibrium magnetization distribution. The spins of the step corner atoms were expected to couple to the spins in the terraces and perhaps cause them to be somewhat canted out-of-plane. This did not occur as a result of the balance between the anisotropy energies of neighboring atoms and the exchange energy which couples them. The out-of-plane anisotropy of the step corner site occurs via the term proportional to $\cos \theta (\sin \theta \sin \varphi + \sin \theta \cos \varphi)$ [i.e., $m_z(m_x + m_y)$]. The minimum energy occurs when $-m_z = m_x + m_y$. This equals zero for $\varphi = 3\pi/4$ ($[1\bar{1}0]$), which is the uniaxial anisotropy axis for the step edge site. Although the anisotropy energy of the step edge and step corner sites are about equal, the coupling via exchange to nearby surface and bulk sites (biaxial $\langle 110 \rangle$) ensures that the step edge site is dominant. For any initial condition on the magnetization the final minimized energy configuration has the spins aligned along the step direction, and the out-of-plane component vanishes with $(\sin \varphi + \cos \varphi)$.

The magnetization configuration is somewhat different for faceted steps and square islands. At the corner joining a $[110]$ step to a $[1\bar{1}0]$ step, the magnetization of each step will be forced away from $\langle 110 \rangle$ by the field due to the other step, resulting in a nonzero out-of-plane component. If the density of facets is large enough or the size of islands small enough a significant out-of-plane remanence will exist. This configuration has been simulated via a square island ($3\text{ nm} \times 3\text{ nm}$) on a $5\text{ nm} \times 5\text{ nm}$ square layer with periodic boundary conditions. The length of the sides of the island was chosen to approximate the length of facets observed in films which exhibited out-of-plane remanence. The out-of-plane component of the calculated average equilibrium magnetization was ~ 0.03 . This was significantly less than the results from Kerr loops shown in Fig. 1.

IV. CONCLUSION

It is apparent from these micromagnetics simulations that the anisotropy of step atoms can not be responsible for

the out-of-plane remanence we observed experimentally. For surfaces with a high density of $\langle 110 \rangle$ facets, this anisotropy may be a contributing factor. This micromagnetics result from semi-infinite parallel $\langle 110 \rangle$ steps agrees with the experimental results from Co deposits on vicinal Cu(1 1 13) surfaces.⁴ The anisotropy switches to biaxial in-plane at increased temperatures.¹³ This may be due to Cu atoms decorating the step edges,¹⁴ or to restructuring of the step edges with rectangular protrusions perpendicular to the original step.¹⁵ In the latter case, micromagnetics simulations reported here predict a small ($\sim 3\%$) out-of-plane component to the magnetization.

Overpotential driven perpendicular magnetization of electrodeposited ultrathin cobalt films

J. L. Bubendorff, E. Beaurepaire, C. Mény, and J. P. Bucher

Institut de Physique et de Chimie des Matériaux de Strasbourg, UMR 46 CNRS, 23 rue du Loess, F-67037 STRASBOURG Cedex, France

Depending on the overpotential applied during electrodeposition of ultrathin cobalt films ($\eta = 0.1$ – 2.2 V), either in-plane or out-of-plane magnetization can be stabilized. The regime of high supersaturation in particular allows to engineer electrodeposited cobalt films on Au(111) that show perpendicular magnetization (in the thickness range from 2 to 8 atomic layers) exactly like their ultrahigh vacuum grown counterparts. The film topography depends on the overpotential as shown by atomic force microscopy: continuous films are obtained at low overpotential whereas high overpotential leads to the formation of islands. The perpendicular magnetization results from a subtle thickness dependent competition between the shape and the interface anisotropy. © 1998 American Institute of Physics. [S0021-8979(98)48111-8]

Adsorption of atoms on a substrate is a nonequilibrium process, the system is temporarily supersaturated and tries to restore equilibrium by forming islands. Nucleation and growth compete to restore equilibrium.¹ Therefore, magnetic properties of growing islands may strongly differ from those of a continuous film and the system becomes truly two dimensional only after the islands have coalesced.²

Compared to physical vapor deposition techniques which rely on costly equipment operating under ultrahigh vacuum (UHV) electrochemical deposition techniques are cheap, versatile, and allow a wide range of parameters to be adjusted for giant magnetoresistance applications^{3,4} and in nanostructured magnetic needles and multilayers with high aspect ratios.^{5,6} Furthermore, high values of supersaturation (which are necessary to precipitate clusters) can be achieved that are ideally adapted to the engineering of nanostructured advanced materials.

In this work, we show how the magnetic anisotropy (the tendency of the magnetization to align along a given direction) of ultrathin, electrodeposited, and Cu covered cobalt films on Au(111) can be tuned continuously from in-plane to out-of-plane by carefully controlling the overpotential $\eta = |U_{\text{applied}} - U_{\text{Co/Co}^{2+}}|$ during deposition in a beaker. We found $U_{\text{Co/Co}^{2+}} = -1.02$ V/mercury sulfate electrode (MSE) (potential quoted versus the mercury sulfate electrode) and the Co deposition starts at $\eta = 0.13$ V.⁷ The configuration with perpendicular magnetization has been stabilized previously only on ultrathin epitaxial films grown in UHV^{8–13} and is of considerable interest for technological applications, in particular magneto-optic data storage.

Gold substrates were prepared by vacuum evaporation of 100-nm-thick gold films onto freshly cleaved mica substrate. Each sample was then flame annealed leading to (111) textured gold films with terraces 100 to 200 nm wide as verified by scanning tunnel microscopy (STM).¹⁴ Electrochemical measurements were conducted in a three electrode cell under potentiostatic mode, with a mercury sulfate electrode (MSE) as a reference and a Pt counter electrode. Solutions of 4×10^{-2} M CoSO_4 and 9×10^{-3} M CoCl_2 , were prepared with reagent grade chemicals in bidistilled water. No additives (such as saccharine¹⁵ or benzotriazole¹⁶) have been

used and pH=4 is achieved by adding H_3BO_4 to the solution. Under the conditions of our experiment, (see Ref. 17 for details) deposits with purity comparable to MBE can be achieved.¹⁸

Bulk deposition of cobalt is performed only after a high quality gold Au(111) electrode has been identified by its characteristic $\sqrt{3} \times 22$ reconstruction and dereconstruction peaks in the cyclic voltammograms (cyclic current–voltage curves).¹⁹ In order to induce widely different growth modes, a set of samples of thicknesses comprised between 1 and 100 AL have been grown at overpotentials between $\eta = 0.18$ and 2.2 V corresponding to deposition rates between 0.15 and 50 AL/s. Cobalt films have been covered *in situ* by an additional 30-AL-thick Cu film after addition of CuSO_4 solution to the base solution, at $\eta = 0$ V (Cu^{2+} ion concentration 5×10^{-4} M deposition rate 0.3 AL/s). The Cu/Co/Au films have finally been emerged from the solution and tested (*ex situ*) for their magnetic and structural properties.

Figure 1 compares the topography of two Co films, 1.5 nm thick, without Cu protection, prepared at $\eta = 0.18$ (a) and 0.68 V (b). After emersion under potentiostatic control ($\eta = 0$ V), the films are directly observed using tapping mode AFM. The deposit made at $\eta = 0.68$ V consists of connected islands with a lateral extension of about 30 nm and average height of 2 to 3 nm. The islands are found to be disconnected for equivalent thicknesses below 1 nm and coalesce with increasing Co thickness, similar to what was observed for UHV grown films.²⁰ For $\eta = 0.18$ V, the Co film is quite continuous since growth is probably initiated at step edges and defects and the Co film follows the topography of the underlying gold substrate.

The local crystallographic structure of the buried Co films has been studied elsewhere²¹ by zero field NMR. At pH=4 and $\eta = 0.68$ V, the films are made of up to 84% hcp cobalt with the *c* axis perpendicular to the Au(111) plane. The remaining 16% are cobalt atoms in a cfc environment. For $\eta = 0.18$ V, the concentration of hcp-Co drops to 77% mainly due to the presence of stacking faults in the hcp phase (11%). The Co/Au interface is found to be very sharp.²¹ In particular, it always involves one complete plane of atomic Co and no intermixing, like in Co/Cu multilayers,²² occurs.

FIG. 1. AFM images of an uncovered 1.5-nm-thick cobalt film as a function of overpotential. (a) $\eta = 0.18$ V, (b) 0.68 V. Clearly seen in the pictures are the flat gold patches, about 500 nm wide, on mica (note dilated z scale) which are covered either by a smooth film of cobalt at low overpotential or granular islands of cobalt at high overpotential.

Magnetic hysteresis loops, in the configuration with the magnetic field perpendicular and parallel to the film plane, have been measured by magneto-optic Kerr effect. Figure 2 shows the hysteresis loops for 3.6-AL-thick Co films, obtained at overpotentials of 0.18 and 0.68 V. At $\eta = 0.18$ V the component of the magnetization is strongest along a direction parallel to the film plane whereas at $\eta = 0.68$ V, the easy direction of the magnetization is perpendicular to the film plane (rectangular shape of the hysteresis loop). The saturation magnetizations $M_s(\eta = 0.18 \text{ V}) = 1250 \pm 180 \text{ G}$ and $M_s(\eta = 0.68 \text{ V}) = 1395 \pm 200 \text{ G}$ as measured by alternating field gradient and superconducting quantum interference device (SQUID) magnetometry are in good agreement with the bulk value $M_s = 1420 \text{ G}$.^{8,9}

The ratio of the remnant magnetization [$M_r = M(H = 0)$] in the perpendicular direction over the saturation magnetization M_s , provides a good measure of the tendency of the system to stabilize the out-of-plane configuration. Figure 3(a) shows M_r/M_s as a function of the film thickness t_{Co} for

FIG. 2. Hysteresis loops recorded by magneto-optical Kerr effect on a 3.6-AL-thick cobalt film. The magnetic field is applied perpendicular (\perp) and parallel (\parallel) to plane. Overpotentials during electrodeposition were $\eta = 0.18$ and 0.68 V, respectively.

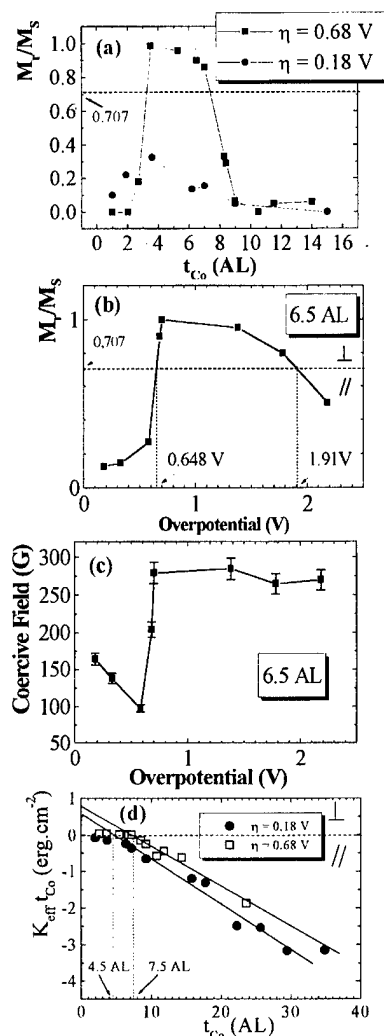

FIG. 3. (a) Ratio of remnant magnetization M_r over saturation magnetization M_s in the perpendicular configuration as a function of film thickness for $\eta = 0.18$ and 0.68 V. (b) M_r/M_s and (c) polar coercive field H_C as a function of η for cobalt films 6.5 AL thick. The continuous increase of M_r/M_s shows the evolution towards fully out-of-plane magnetization $H_C = 280 \text{ G}$ at overpotentials $\eta \geq 0.68 \text{ V}$. (d) Product of the effective anisotropy (K_{eff}) and the film thickness (t_{Co}) as a function of t_{Co} for $\eta = 0.18$ and 0.68 V. The slopes of the curves lead to K_u while K_s is the intercept at $t_{\text{Co}} = 0$.

two widely different deposition rates. The ability of high growth rates to stabilize the out-of-plane configuration for $3 \text{ AL} < t_{\text{Co}} < 7 \text{ AL}$ (M_r/M_s is close to 1) appears clearly while the out-of-plane magnetization is never stable in films deposited at low deposition rates at room temperature. The drop of M_r/M_s at large t_{Co} is attributed to the fact that shape anisotropy, which tends to align the magnetization in the film plane, overcomes the surface and magnetocrystalline anisotropy. The significant role of the overpotential η applied during deposition on the magnetic properties is evidenced in Fig. 3(b) (case of 6.5 AL film). After a steep increase for $\eta > 0.6 \text{ V}$, M_r/M_s reaches a value of 1 and the magnetization remains perpendicular for $0.65 < \eta < 1.9 \text{ V}$. The coercive field H_C [Fig. 3(c)] reached a saturation value of 280 G at $\eta = 0.68 \text{ V}$, close to the values obtained for films grown under UHV.⁸⁻¹³ Further optimization in the sample preparation process (ion concentration, gold surface preparation

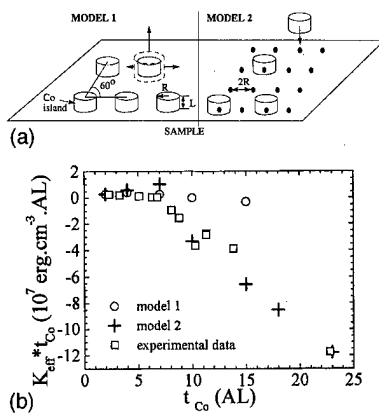

FIG. 4. (a) Models 1 and 2 for the growth of Co films at $\eta=0.68$ V. (b) Comparison between experimental data and the calculated values of $K_{\text{eff}}t_{\text{Co}}$ vs t_{Co} .

prior to deposition) may contribute to an increase in H_C , and make these films attractive for magneto-optical data-storage applications.

To obtain quantitative information about the magnetic anisotropy, we first assume flat, continuous, cobalt structures with uniaxial anisotropy, and express the total energy as $E = -\mathbf{M} \cdot \mathbf{H} + K_{\text{eff}} \sin^2 \vartheta$, where K_{eff} is an effective anisotropy term and ϑ is the angle between the magnetization and the normal to the film plane. The effective anisotropy can be quantified by calculating the area between perpendicular and parallel magnetization curves (first order approximation)²³ and may be written as the sum of three terms:⁷ $K_{\text{eff}} = K_v + \beta K_s/t_{\text{Co}} - 2\pi\alpha M_s^2$, where K_v is a volume, K_s an interface contribution (accounting for Co/Cu and Co/Au interfaces), $2\pi\alpha M_s^2$ the shape anisotropy, and α and β two parameters depending on the film topography. When the film is continuous and planar, α and β are strictly equal to 1. A thickness dependent competition between the volume and interface term and the shape anisotropy occurs leading to perpendicular (respectively, in-plane) magnetization when K_{eff} is positive (respectively, negative). Figure 3(d) represents $K_{\text{eff}}t_{\text{Co}}$ versus t_{Co} for films prepared at $\eta=0.18$ and 0.68 V. At $\eta=0.68$ V, the slope of the curve in Fig. 3(d) (in the regime $t_{\text{Co}} > 8$ AL) leads to $K_v = 670$ kJ/m³ and $K_s = 0.8$ mJ/m². The slope of the curve changes abruptly at $t_{\text{Co}} = 7$ AL and K_{eff} turns positive below 7 AL, leading to perpendicular magnetization. For deposits made at $\eta=0.18$ V, ($K_v = 370$ kJ/m³ and $K_s = 0.6$ mJ/m²), on the contrary, K_{eff} goes smoothly to zero but remains always negative. Our value of K_v and K_s are in good agreement with known values obtained by the same analysis for MBE grown films.^{10,12,13}

At low coverages when the films are discontinuous, β is different from 1 and decreases with the increasing proportion of uncovered gold surface. β can be taken as the proportion of covered gold surface while α depends on the shape of cobalt islands. On the basis of AFM images for $\eta=0.68$ V, and in order to get numerical inputs for the expression of K_{eff} we now assume cylindrical islands of height L and radius R that are distributed on a hexagonal lattice [see Fig. 4(a)]. Expressions of α have been given as a function of $L/2R$.²⁴ For $t_{\text{Co}} = 2$ AL, the AFM images lead to a density $D = 15$ nucleation centers per μm^2 , average values of L and R are,

respectively, 1.7 and 7 nm. In the following, two models are considered corresponding respectively to instantaneous and progressive nucleation [Fig. 4(a)]. *Model 1* considers that the cylindrical islands grow laterally and vertically, in such a way that the ratio $L/2R$ and the number of islands remains constant (instantaneous nucleation). α takes the value 0.65 and β changes as a function of Co coverage. At coalescence, α becomes equal to 1, therefore the shape anisotropy dominates K_{eff} at high coverage. *Model 2* describes in a simplified way the progressive nucleation. Cobalt islands are added stepwise on a hexagonal lattice [see Fig. 4(a)]. The nucleation rate and the ratio $L/2R$ are constant. The islands grow until they reach a thickness $L = 7.5$ AL. As shown on Fig. 4(b), both models reproduce correctly the positive value of $K_{\text{eff}}t_{\text{Co}}$ at low Co coverage as well as the slope change of $K_{\text{eff}}t_{\text{Co}}$ versus t_{Co} when islands coalesce. The progressive nucleation however seems to fit the data better at higher coverage.

In the case of Co deposited at $\eta=0.18$ V, the best approximation consists in taking $\alpha=1$ (since the deposits are flat and laterally extended), while β is allowed to change with the Co coverage. Since β is small at low coverage, the in-plane shape anisotropy remains dominant at any thickness. It is mainly the topographic difference between films prepared at $\eta=0.18$ and 0.68 V that leads to different t_{Co} dependent variations of the shape and interface anisotropy. In this respect, our model could also be applied to UHV grown films where "3D" islands formed in the first growth stage.²⁰

Magnetic and structural characterizations of HCP permalloy films grown by molecular beam epitaxy

J. C. A. Huang,^{a)} Y. M. Hu, and C. C. Yu

Physics Department, National Cheng-Kung University, Tainan, Taiwan 70101, Republic of China

An hcp metastable phase of $\text{Ni}_{80}\text{Fe}_{20}$ ($1\bar{1}00$) structure has been grown as high-quality epitaxial films on $\text{Co}(1\bar{1}00)$ and $\text{Cr}(211)$ planes. The epilayers of $\text{Ni}_{80}\text{Fe}_{20}$ grow as hcp structure up to a critical thickness of ~ 100 Å, and the further layers transform to twinned fcc structure. Magneto-optical Kerr effect study indicates that the hcp $\text{Ni}_{80}\text{Fe}_{20}$ ($1\bar{1}00$) layers exhibit strong crystalline induced uniaxial magnetic anisotropy with easy axis along the hcp[0001] direction. The subsequent fcc $\text{Ni}_{80}\text{Fe}_{20}$ layers show decreasing coercive fields as the film thickness increased. For the thick fcc film, interestingly, the magnetic easy axis shifts 90° with respect to that of the underlying hcp layers. The result is explained by the shape anisotropy effect due to the formation of quasi-1D columnar islands directed perpendicular to the hcp[0001] direction. © 1998 American Institute of Physics. [S0021-8979(98)53711-5]

Surface magnetism has attracted much attention in recent years because of fundamental research and advanced technological applications. The orientation of magnetization for a ferromagnetic thin film can often be determined by the competition between magnetocrystalline anisotropy, shape anisotropy, and surface or interface anisotropy, etc.¹ There has also been an increasing interest in understanding the relationship between the magnetic anisotropies and the crystal structures. It has been demonstrated that the crystal structure and magnetic anisotropy (MA) of the magnetic thin films may depend strongly on the underlying substrates or buffer layers.^{2,3}

In a previous work, the authors reported the magnetic properties of Co/Cr films and multilayers.⁴⁻⁷ In this investigation we study the novel fabrication and structural transformation (hcp to fcc) of metastable hcp $\text{Ni}_{80}\text{Fe}_{20}$ ($1\bar{1}00$) films grown on $\text{Co}(1\bar{1}00)$ and $\text{Cr}(211)$. We demonstrate here the control of crystal structure and MA of $\text{Ni}_{80}\text{Fe}_{20}$ films by selecting suitable buffer layers and by varying the film thickness. Presently, we assess the degree to which any of the results is predictable.

The crystal growth was carried out in a vacuum product made molecular beam epitaxial (MBE) chamber equipped with four *e*-beam sources. This MBE chamber allowed sample transfer under ultrahigh vacuum (UHV) condition to an analysis chamber for morphological and magnetic characterizations by AFM and MOKE. Details of the MBE chamber in which epitaxial growth and surface characterization took place were described elsewhere.⁸ The $\text{Co}(1\bar{1}00)$ was prepared on $\text{Cr}(211)/\text{Mo}(211)$ seeding layers using epitaxial grade $\text{Al}_2\text{O}_3(1\bar{1}00)$ or $\text{MgO}(110)$ substrates.⁴⁻⁷ The initial $\text{Mo}(211)$ and $\text{Cr}(211)$ buffer layers of ~ 100 Å were grown at 900 and 350 °C, respectively, followed by $\text{Co}(1\bar{1}00)$ layers ~ 100 Å thick at 300–350 °C. The hcp $\text{Ni}_{80}\text{Fe}_{20}(1\bar{1}00)$ films

were grown on the fresh $\text{Co}(1\bar{1}00)$ [or directly on $\text{Cr}(211)$] plane at the optimal growth temperatures which ranged from 100 to 300 °C.

The crystal structure and quality were characterized by reflection high energy electron diffraction (RHEED) and x-ray diffraction (XRD). The correlation between the structural and magnetic properties was investigated by magneto-optical Kerr effect (MOKE) technique. Longitudinal (LMOKE) and polar (PMOKE) configurations of MOKE were employed to determine the in-plane and out-of-plane magnetization loops of the samples. Note that the penetration depth⁵ of the He–Ne laser for the MOKE experiment is about 150 Å, surface layers can be conveniently probed by MOKE during epitaxial growth.

By RHEED and XRD studies we have determined the following orientation relations:

$$\begin{aligned} &\text{Ni}_{80}\text{Fe}_{20}(211) \parallel \text{Ni}_{80}\text{Fe}_{20}(1\bar{1}00) \parallel \text{Co}(1\bar{1}00) \parallel \text{Cr}(211) \parallel \text{Mo}(211) \parallel \\ &\text{Al}_2\text{O}_3(1\bar{1}00); \\ &\text{Ni}_{80}\text{Fe}_{20}[0\bar{1}1] \parallel \text{Ni}_{80}\text{Fe}_{20}[11\bar{2}0] \parallel \text{Co}[11\bar{2}0] \parallel \text{Cr}[\bar{1}11] \parallel \text{Mo}[\bar{1}11] \parallel \\ &\text{Al}_2\text{O}_3[0001]; \\ &\text{Ni}_{80}\text{Fe}_{20}[\bar{1}11] \parallel \text{Ni}_{80}\text{Fe}_{20}[0001] \parallel \text{Co}[0001] \parallel \text{Cr}[0\bar{1}1] \parallel \text{Mo}[0\bar{1}1] \parallel \\ &\text{Al}_2\text{O}_3[1120]. \end{aligned}$$

The crystal structure and magnetic property of $\text{Co}(1\bar{1}00)$ on $\text{Cr}(211)$ had been described elsewhere.⁴⁻⁷ Schematic diagrams of the epitaxial relations and lattice geometry between hcp $\text{Ni}_{80}\text{Fe}_{20}(1\bar{1}00)$ and fcc $\text{Ni}_{80}\text{Fe}_{20}(211)$ are provided in Fig. 1.

On the $\text{Co}(1\bar{1}00)$ surface, RHEED studies show that hcp $\text{Ni}_{80}\text{Fe}_{20}(1\bar{1}00)$ film can be stabilized up to a critical thickness (t_c) of ~ 100 Å, and the further epilayers transform to fcc structure, as shown in Figs. 2(b)–2(d). The RHEED image of the $\text{Co}(1\bar{1}00)$ plane is shown in Fig. 2(a) for comparison. Detailed RHEED measurements (for all principle azimuths) indicate that the hcp $\text{Ni}_{80}\text{Fe}_{20}(1\bar{1}00)$ and $\text{Co}(1\bar{1}00)$ films possess much alike crystal symmetry and lattice parameters. With increasing fcc $\text{Ni}_{80}\text{Fe}_{20}$ layer thickness to about 500 Å, the RHEED patterns remained almost unchanged for the beam directed along the $\text{Ni}_{80}\text{Fe}_{20}[\bar{1}11]$ azimuth. How-

^{a)}Electronic mail: jcahuang@mail.ncku.edu.tw

FIG. 1. Schematic diagrams showing the epitaxial relations, lattice geometry, and the stacking sequence for both hcp(1100) and subsequent fcc(211) layers (after phase transformation) along the close-packed direction. A twin boundary in fcc layers is shown as a consequence of stacking fault.

ever, for the beam directed along the $\text{Ni}_{80}\text{Fe}_{20}[\bar{0}11]$ azimuth the RHEED pattern developed into two sets of angled streaks [shown in Fig. 2(f)], indicating the faceting growth of twinned $\{111\}$ planes (indexed as $\{111\}_\alpha$ and $\{111\}_\beta$ in Fig. 1). Accordingly, the surface morphology changed from the isotropiclike characteristic into a clear quasi-1D feature with columns quite uniformly directed along the $\text{fcc}[\bar{0}11]$, as displayed in Figs. 4(a) and 4(b), respectively. The growth of the twinned $\text{fcc}\{111\}$ plane is more favorable than that of (211) surface owing to the reduction of surface energy. Note that the angle of the RHEED streaks is consistent with a $\{111\}$ facet of a (211) surface.

Note that hcp $\text{Ni}_{80}\text{Fe}_{20}(1\bar{1}00)$ films can also be stabilized up to ~ 100 Å on Cr(211) plane. Tilt XRD scans on 100 Å $\text{Ni}_{80}\text{Fe}_{20}$ on Cr(211) samples [Fig. 3(a)] reveal that the lattice spacings of hcp $\text{Ni}_{80}\text{Fe}_{20}$ are $a = 2.50$ Å, $c = 4.07$ Å, very close to those of the hcp Co ($a = 2.51$ Å, $c = 4.07$ Å) and those for the unit cell of Cr(211) plane (2.49 Å \times 4.07 Å). The growth of metastable hcp $\text{Ni}_{80}\text{Fe}_{20}$ could be

FIG. 2. RHEED patterns for (a) 100 Å Co($\bar{1}100$), and the subsequent $\text{Ni}_{80}\text{Fe}_{20}$ layers of (b) 50 Å, (c) 100 Å, (d) 150 Å, (e) 200 Å, and (f) 500 Å thick. The RHEED beam was directed parallel to the $\text{Co}[1\bar{1}20]$ ($\parallel\text{Ni}_{80}\text{Fe}_{20}[1\bar{1}20]\parallel\text{Ni}_{80}\text{Fe}_{20}[0\bar{1}1]$) azimuth.

FIG. 3. Tilt (h, k, l) x-ray diffraction spectra scanned from $h = -2.5$ to $h = 2.5$ [$k = 0$, $l = (1\bar{1}00)$] for $\text{Ni}_{80}\text{Fe}_{20}(\text{Py})$ films grown on Cr(211) seed layers: (a) $\text{Py} = 100 \text{ \AA}$ and (b) $\text{Py} = 1000 \text{ \AA}$.

due to the smallness of the energy difference between the fcc and hcp phases for most 3d transition metals.⁹ In addition, we point out that similar phase transformation process was also observed in Ni₈₀Fe₂₀ films grown on Cr(211), though the growth of twinned {111} planes occurred at higher thickness of ~ 700 Å due to the surface roughness of the Cr(211). The twinned fcc(211) structure for thick Ni₈₀Fe₂₀ layers was confirmed by the tilt XRD spectrum shown in Fig. 3(b). These results suggest a general pathway for structure and morphology transformations from hcp(1100) to fcc(211). It is noted that Harp¹⁰ *et al.* reported a fcc \rightarrow hcp phase transition mechanism in Co where transformation occurs by the

FIG. 4. The AFM image of (a) 100 Å and (b) 500 Å thick $\text{Ni}_{80}\text{Fe}_{20}$ layers grown on $\text{Co}(1\bar{1}00)$, the columnar direction of the quasi-1D-like islands in (b) is determined as parallel to $\text{fcc Ni}_{80}\text{Fe}_{20}[0\bar{1}1]$.

FIG. 5. The angular dependent LMOKE hysteresis loops for (a) 100 Å Co(1100) and the subsequent $\text{Ni}_{80}\text{Fe}_{20}$ layers of (b) 100 Å and (c) 500 Å thick. The applied magnetic field is along $\text{Co}[11\bar{2}0]$ ($\parallel \text{hcpNi}_{80}\text{Fe}_{20}[11\bar{2}0] \parallel \text{fccNi}_{80}\text{Fe}_{20}[011]$) direction for 90° azimuth, and along $\text{Co}[0001]$ ($\parallel \text{Ni}_{80}\text{Fe}_{20}[0001] \parallel \text{Ni}_{80}\text{Fe}_{20}[\bar{1}11]$) direction for 0° azimuth.

slipping of $\{111\}$ planes along a $\langle 11\bar{2} \rangle$ direction, which is essentially a reverse process of the case discussed here.

Figures 5(a)–5(b) display the angular dependent LMOKE hysteresis loops of 100 Å Co (1100) and subsequent 100 Å $\text{Ni}_{80}\text{Fe}_{20}$ (1100) (hcp), respectively. Both magnetic layers are difficult to be magnetized along the out-of-plane directions because no PMOKE signal was observed. LMOKE measurements show that the hcp $\text{Ni}_{80}\text{Fe}_{20}$ layers exhibit uniaxial MA with large coercive field ($H_c > 80$ Oe) and easy axis along the $\text{hcp}[0001]$, much like the underlying hcp Co layers because large coercive fields and MA constants ($K_{u1} \sim 10^5$ ergs/cm³) were measured in hcp $\text{Ni}_{80}\text{Fe}_{20}$ on Cr(211).¹¹ Thus we believe that the strong MA in hcp $\text{Ni}_{80}\text{Fe}_{20}$ layers [on Co(1100)] could be partly resulted from the magnetocrystalline effect in addition to the exchange coupling effect to the underlying Co layers.

With increasing the $\text{Ni}_{80}\text{Fe}_{20}$ layer thickness above 100 Å, the H_c gradually decreases to ~ 20 –25 Oe though the direction of the easy axis remains unchanged ($\parallel \text{fcc}[\bar{1}11] \parallel \text{hcp}[0001]$). Interestingly, the magnetic easy axis shifts to $\text{fcc}[011]$ (perpendicular to $\text{fcc}[\bar{1}11]$ and $\text{hcp}[0001]$) for $\text{Ni}_{80}\text{Fe}_{20}$ layers of about 500 Å thick, as shown in Fig. 5(c). Note that the shift of the magnetic easy axis in the thick fcc layers coincides with the faceting growth of $\{111\}$ twins [see Fig. 2(f)] and the formation of quasi-1D-like columnar structure [Fig. 4(b)]. Therefore, we believe that the change of magnetic easy axis in the thick fcc $\text{Ni}_{80}\text{Fe}_{20}$ layers are induced by the strong shape anisotropy effect.

The transport and magnetic properties of magnetite (Fe_3O_4) thin films grown epitaxially on single crystal $\text{MgO}(100)$ and $\text{SrTiO}_3(100)$ substrates, and with multiple grain orientations on polycrystalline SrTiO_3 substrates, have been investigated. The films are grown using pulsed laser deposition and their epitaxial quality determined using ion channeling measurements. Transport and magnetic studies of Fe_3O_4 films as a function of thickness and morphology suggest that epitaxial strain and growth defects affect the width and temperature of the Verwey transition. In addition, these factors also significantly influence the magnetic coercivity of the films. The low-field magnetoresistance (MR) behaviors of epitaxial and polycrystalline films as a function of temperature have been compared and they were found to be quite similar, suggesting very small contribution to the MR from grain boundaries. © 1998 American Institute of Physics. [S0021-8979(98)17911-2]

I. INTRODUCTION

Magnetite (Fe_3O_4) has the so-called cubic inverse spinel structure in which the Fe cations occupy interstices of a face-centered-cubic (fcc) close packed frame of oxygen ions. The eight tetrahedral (*A*) sites are solely occupied by Fe^{3+} , while the 16 octahedral (*B*) sites are equally shared by Fe^{3+} and Fe^{2+} ions. Rapid hopping of electrons between Fe^{2+} and Fe^{3+} ions in the *B* sites results in good room-temperature conductivity. Upon cooling, bulk Fe_3O_4 undergoes a metal-insulator transition (Verwey transition) at a temperature $T_v \sim 120$ K, where the electron hopping is frozen and the conductivity decreases by about two orders of magnitude.¹ Although it is generally accepted that the transition is due to the ordering of the Fe^{3+} and Fe^{2+} ions,^{1,2} the mechanism governing the transport and magnetic properties of this material above and below the transition is not yet well understood.

A number of differences has been observed in the transport and magnetic properties of thin films as compared to bulk magnetite. In particular, the Verwey transition is broadened and shifted to lower temperatures in the case of the former. This has been ascribed to the interaction between the film and the substrate, resulting in stress and rigid structural coupling of the film.^{3,4} Differences in the saturation magnetization and coercivity of thin films and bulk samples have also been reported.^{5,6} In this work, we have determined the crystallinity of Fe_3O_4 films grown on different substrates using ion channeling, and subsequently studied their temperature-dependent transport, magnetic, and magnetoresistance properties as a function of film thickness and morphology.

II. EXPERIMENT

The magnetite films have been grown on (100)-oriented MgO and SrTiO_3 single crystals and on polycrystalline SrTiO_3 substrates using the pulsed laser deposition technique. The polycrystalline SrTiO_3 substrates, with 3 μm average grain size, are obtained by cutting and optically polishing sintered pellets (97%–98% density) of the material.⁷ The Fe_3O_4 target used for the ablation has been prepared by a standard solid-state reaction method. A focused KrF excimer laser (248 nm) beam has been used for ablation, with a repetition rate of 4 Hz and fluence of ~ 2 – 3 J/cm² at the target. Prior to deposition, the substrates are heated to 750 °C and the surface cleaned using a 100 eV Ar ion beam. The films are then grown at a temperature of 350 °C in vacuum ($\sim 10^{-6}$ Torr). Following growth, the films are cooled down to room temperature at a rate of 15 °C/min. Some of the films have also been deposited using a frequency-tripled Nd:YAG laser (355 nm) and have been found to exhibit very similar transport and magnetic properties to those grown using the KrF laser.⁶ The film thicknesses, after deposition, have been determined using Rutherford backscattering spectroscopy (RBS). The standard four-probe dc method has been used for the resistivity measurements, while the magnetic measurements have been carried out using a superconducting quantum interference device (SQUID) magnetometer.

III. RESULTS AND DISCUSSION

We have investigated the crystalline quality of the Fe_3O_4 films grown on single crystal MgO and SrTiO_3 substrates by

FIG. 1. Rutherford backscattering spectrum showing counts vs backscattering energy for both channeling and random 2.3 MeV $^4\text{He}^+$ ions backscattered from a Fe_3O_4 film on a $\text{MgO}(100)$ substrate.

ion channeling spectroscopy. Figure 1 shows the $\langle 100 \rangle$ aligned and random RBS spectra (2.3 MeV $^4\text{He}^+$ ions) for a Fe_3O_4 film on $\text{MgO}(100)$. The ratio (χ_{\min}) of the backscattered yield along $\langle 100 \rangle$ to that in a random direction is 6.0%. Previous transmission electron microscopy measurements of Fe_3O_4 films grown on $\text{MgO}(100)$ have also confirmed epitaxial growth of the film, with the $\langle 100 \rangle$ and $\langle 010 \rangle$ axes aligned with the respective cubic axes of the substrate.⁶ For the film grown on the $\text{SrTiO}_3(100)$ substrate, χ_{\min} has been measured to be 17.4%, suggesting that it has a lower crystalline quality than the film grown on MgO .

Figure 2 displays the resistance (R) as a function of temperature for Fe_3O_4 films grown on $\text{MgO}(100)$ substrates with different thicknesses. Overall, the films exhibit a broadened Verwey transition as compared to measurements reported for bulk samples. The transition is the sharpest for the 6600 Å thick film, with a transition temperature (T_v) of about 121 K. This is determined from the maximum in the slope of the Arrhenius plot for thermally activated hopping transport [$\ln(R/T)$ vs $1/T$]. The resistance change at the transition decreases in magnitude and the transition gets broader with decreasing film thickness, and is not noticeable for the thinnest films. The transition temperature, as determined from the Arrhenius plot, is plotted as a function of film thickness and shown as an inset in Fig. 2. T_v increases quite rapidly with the initial increase in film thickness and then

FIG. 2. Resistance as a function of temperature for Fe_3O_4 films with different thicknesses. The Verwey transition temperature (T_v) determined from Arrhenius plots as a function of film thickness is shown in the inset.

FIG. 3. Resistivity as a function of temperature for ~ 850 Å thick Fe_3O_4 films grown on $\text{MgO}(100)$, $\text{SrTiO}_3(100)$, and polycrystalline (3 μm average grain size) substrates.

gradually levels off at a value close to the bulk. The broadening and reduction in T_v for the thinner films is possibly caused by the residual strain in the films resulting from the lattice mismatch with the substrate. The growth of Fe_3O_4 , which has a slightly smaller lattice parameter than that of the MgO substrate, results in an in-plane expansion of the Fe_3O_4 lattice accompanied by Poisson compression in the perpendicular direction. A similar behavior has been observed in Fe_3O_4 films grown by molecular beam epitaxy (MBE) and reactive sputter deposition.^{4,5} Besides substrate-induced stress, Van De Veerdonk *et al.* have suggested that the rigid structural coupling between the magnetite film and the cubic lattice of the substrate also suppresses the orthorhombic deformation accompanying the Verwey transition leading to a depressed T_v .⁴

We have also investigated the influence of film morphology on the resistivity behavior of Fe_3O_4 . For this purpose, we have compared the transport and magnetic properties of ~ 850 Å thick film of Fe_3O_4 grown on (100)-oriented MgO and SrTiO_3 single crystals and on polycrystalline SrTiO_3 substrates. The resistivity (ρ) as a function of temperature for the three films is plotted in Fig. 3. It is interesting to note that the value of ρ is comparable over the measured temperature range for the three films. Nonetheless, the epitaxial film on MgO exhibits the sharpest transition, although with a T_v lower than those for the epitaxial and polycrystalline films grown on SrTiO_3 . The higher T_v for the films on SrTiO_3 can be understood based on the lattice mismatch between the film and the substrate. Because of the close lattice match between Fe_3O_4 and MgO (lattice mismatch, $\eta = 3.3 \times 10^{-3}$), the film grows coherently until a critical thickness (t_c) is reached. Based on the shear modulus and elastic modulus, Van De Veerdonk *et al.* have estimated t_c to be about 200 Å for film growth on MgO .⁴ Above t_c , the growth becomes incoherent, with partial or complete relaxation of the strain by formation of misfit dislocations. The lattice mismatch is significantly larger ($\eta = -70 \times 10^{-3}$) for growth on SrTiO_3 , resulting in incoherent growth without any strain for any film thickness. The lower T_v for growth on MgO could be interpreted as resulting from some residual strain in the film, even when it is above the critical thickness. Although the films on SrTiO_3 are unstrained and have higher T_v , the higher con-

centration of defects in the films results in a broadened transition, particularly for the polycrystalline film.

Figure 4 plots the in-plane magnetic hysteresis loops measured at room temperature for the three films discussed above. The field is applied along the $\langle 100 \rangle$ direction for the films on single crystal substrates. It is interesting to note that the film on $\text{SrTiO}_3(100)$ exhibits a higher coercivity (H_c) than the film on $\text{MgO}(100)$. The polycrystalline film has even higher H_c and displays a much more gradual and rounded hysteresis loop than the epitaxial films. This would be expected for the average of a random orientation of grains. We speculate that the higher H_c of the films on SrTiO_3 as compared to MgO is related to the absence of strain in the case of the former.

We finally briefly discuss the low-field magnetoresistance (MR) properties of the epitaxial Fe_3O_4 film grown on MgO and the polycrystalline film grown on the polycrystalline SrTiO_3 substrate. Figure 5 shows the MR ratio at 1500 Oe as a function of temperature for the two films. The resistance hysteresis loop for the polycrystalline film at 123 K is shown as an inset. The MR ratio is defined according to $\Delta R/R = (R_p - R_{1500})/R_{1500}$, where R_p is the peak resistance which occurs at the coercive field, and R_{1500} is the resistance at 1500 Oe. The MR behavior for the two films is quite similar, with a peak occurring close to T_v , as has also been previously observed.^{6,8} Consistent with the transport and magnetic data, the MR peak occurs at a slightly higher temperature and is somewhat broader for the polycrystalline film on SrTiO_3 than for the epitaxial film on MgO . Interestingly, there is very small MR associated with the grain boundaries in the polycrystalline film. This is unlike the behavior of manganite films, where a relatively large low-field MR has been observed below the Curie temperature.⁷ The low-field MR in the manganites has been attributed to spin-dependent transport of polarized electrons at the grain boundaries which serve as pinning centers for the magnetic domain walls. A similar behavior would have been expected for Fe_3O_4 based on the half-metallic behavior of its conduction electrons. However, unlike manganites, the grain boundary resistance in Fe_3O_4 is quite insignificant as evidenced from Fig. 3, thereby possibly resulting in a stronger coupling between the grains. Additional work is needed to further clarify the role of grain boundaries in the MR behavior of Fe_3O_4 and other half-metallic systems.

FIG. 5. Magnetoresistance at $H=1500$ Oe as a function of temperature for a polycrystalline (850 Å thick) and an epitaxial (1500 Å thick) Fe_3O_4 film. The resistance hysteresis as a function of magnetic field for the polycrystalline film at 123 K is shown in the inset.

IV. SUMMARY

In summary, we have measured the crystallinity of Fe_3O_4 films grown on (100)-oriented MgO and SrTiO_3 substrates using ion channeling spectroscopy. The results show that the films grow epitaxially on both substrates, with those grown on MgO exhibiting better crystallinity because of the smaller lattice mismatch. Polycrystalline films with multiple grain orientations have also been grown on intentionally fabricated polycrystalline SrTiO_3 substrates. The Verwey transition and the magnetic coercivity are strongly influenced by the thickness and morphology of the films, which we primarily attribute to the residual strain in the films. The low-field magnetoresistance behavior of the epitaxial and polycrystalline films has also been studied, and the MR magnitude has been found to be quite small ($\sim 2\%$ – 3% at 1500 Oe) for both the films, with very little contribution resulting from grain boundary transport.

We have fabricated ferromagnet-insulator-ferromagnet junctions using a ramp-edge geometry based on $(\text{La}_{0.7}\text{Sr}_{0.3})\text{MnO}_3$ ferromagnetic electrodes and a SrTiO_3 insulator. Pulsed laser deposition was used to deposit the multilayer thin films and the devices were patterned using photolithography and ion milling. As expected from the spin-dependent tunneling, the junction magnetoresistance is dependent on the relative orientation of the magnetization in the electrodes. A junction magnetoresistance (JMR) as large as 30% is observed at low temperatures and low fields. In addition, we have found that JMR is reduced at high temperatures ($T > 100$ K) and decreases monotonically with increasing field at high fields ($0.5 \text{ T} < H < 1 \text{ T}$). Possible causes for these are also discussed. © 1998 American Institute of Physics. [S0021-8979(98)20411-7]

There has been a great deal of interest in magnetic tunnel junctions based on conventional ferromagnetic metals due to the large junction magnetoresistance (JMR) observed at room temperature.¹ Due to the uneven spin distribution of conduction electrons at the Fermi level in the ferromagnets, one can expect tunneling probability to be dependent on the relative magnetization orientation of the ferromagnet electrodes. By assuming that spin is conserved in the tunneling process and tunneling current is dependent on the density of states at Fermi level of two electrodes, Jullier showed the maximum change in the tunneling resistance (ΔR) as²

$$\Delta R/R_A = (R_A - R_P)/R_A = 2P_1P_2/(1 + P_1P_2),$$

where R_A and R_P are the junction resistances when the magnetizations are antiparallel and parallel, respectively, and P_1 and P_2 are the spin polarizations of the two electrodes.

Recently, doped manganites, $(\text{R}_{0.7}\text{M}_{0.3})\text{MnO}_3$ where R is a rare earth element such as La, Pr, and Nd, and M is a divalent element such as Ba, Sr, and Ca, have been rediscovered due to the large magnetoresistance near the metal-insulator transition temperature.³ One of the most intriguing facts of the doped manganites is the half-metallic nature predicted by the strong Hund's coupling and a relatively narrow carrier conduction band.⁴ A half-metallic ferromagnet has 100% spin polarization for conduction electrons, and thus it offers potential as a ferromagnetic metal electrode in devices based on spin-dependent transport effects. Hence, compared to the tunneling junctions based on the conventional ferromagnetic metal electrodes, MR in the tunneling junctions made of the manganites is expected to be larger. Sun *et al.* have demonstrated the existence of large magnetoresistance at low fields and low temperatures in the trilayer sandwich junctions using doped manganites.⁵

We report on the fabrication and characterization of ramp-edge ferromagnet-insulator-ferromagnet junction devices using $(\text{La}_{0.7}\text{Sr}_{0.3})\text{MnO}_3$ (LSMO) and SrTiO_3 (STO) as

the ferromagnet and insulator layers, respectively. A large junction magnetoresistance ($\text{JMR} = [(R_j(H) - R_j(1000 \text{ Oe})) / R_j(1000 \text{ Oe})]$) of 30% is obtained at low temperatures in fields of 200 Oe. The junction magnetoresistance is observed to be dependent on the relative orientation of the magnetization in the electrodes as expected from the spin-dependent tunneling. Various possibilities to affect the device performance are discussed such as the changes in the magnetization process and the reduction of the spin polarizability in the electrodes.
